- Moving away from the center of the 'heatmap', there are a number of reform areas where the Fund has no comparative advantage. As these are areas where there is also less likely to be widespread demand across the membership, the Fund should actively seek to collaborate with and leverage other institutions' expertise to provide country-specific analysis (such as innovation or product market reforms (OECD) or agriculture (World Bank)).
- There are however two areas at the center of the 'heatmap'—labor market and infrastructure—that may not be traditional for the Fund or where the Fund may not have established expertise, but are more likely to have a significant bearing on macroeconomic performance for a 'critical mass' of the membership (Figures 14-15). In this context, the Fund may need to scale up its efforts, building on existing or developing new in-house expertise.

**49. Four complementary tracks of future work can help move this agenda forward**, with a view to developing a deeper understanding of the likely impact of reforms and importantly country needs, as well as enhancing the information and diagnostic tools available for surveillance.

- *Country needs:* To ensure that the Fund's approach reflects more fully a "bottom up" diagnosis of country needs, staff will look to engage more directly with country authorities to better understand the "demand side" of macro-relevant structural reforms. Also, staff will systematically

catalogue the coverage of structural issues, and identify good practices, in recent Article IV reports.

- *Ongoing analytical work:* Staff will continue analytical work across the Fund on the various macroeconomic effects of structural reforms, guided by the Fund's mandate and principles outlined in this paper. That is not to say that all research and policy development should mirror the 'heatmap.' Indeed, and as noted earlier, the complexity of the relationship between structural reforms and macroeconomic outcomes warrants further examination.
  - Ongoing analytical work across the Fund will reinforce efforts to build expertise on specific structural issues. Labor and product market reforms feature prominently in the near-term research agenda of both functional and area departments. For instance, further work on labor and product market reforms in the Spring 2016 WEO and by the European Department. Another possible area for further work would be on successfully addressing infrastructure gaps in EMs.
  - Beyond this, future work should also consider expanding the analysis in this paper to focus on other non-TFP benefits of reform, such as resilience (particularly important given the central role of stability in the Fund's mandate), financial stability (including the relationship between financial development/deepening and reform), and inclusive growth. Also, while the empirical work in this paper provides some tentative insights regarding the timing and durability of the impact on productivity of various reforms, it also suggests the need for further research before they can be affirmed definitively.
  - The same is true concerning the insights gained, largely from the country cases, on aspects of implementation. Here, possible areas of future work could consider the role of initial conditions, the interaction between structural reforms and other levers of macroeconomic policy, the timing of reforms, or the costs associated with implementing reforms.
- *Toolkit and operational issues:* Staff will consider modalities and processes to more explicitly incorporate macrostructural issues in the review process and to more actively support country teams. In the context of building a macrostructural toolkit to help staff leverage analytical work and cross-country experiences, an immediate priority will be to put in place mechanisms to disseminate existing analytical work and policy experiences (including the material in Annex I and drawing on ongoing work to identify good practices in recent Article IV reports).
- *Interagency collaboration:* Based on the preliminary understanding (above) of where the Fund needs to build its own expertise and where the Fund should leverage the expertise of other institutions, staff will develop clearer protocols and modalities for inter-agency collaboration. Where possible, staff will look to build on, or draw lessons from, existing dialogue (e.g., with the OECD on product and labor market issues).

**50. As part of a broader and longer term agenda, staff will look for opportunities to keep the Board apprised of the various elements of this work.** The next major opportunity to engage the Board will be in the context of the 2017 interim assessment of TSR implementation, at which time staff will assess progress on these four tracks of work on structural reforms and, if necessary, identify the need for any reorientation of approach ahead of the 2019 TSR.

## ISSUES FOR DISCUSSION

- 51.** Do Directors find the approach outlined above a useful device to help prioritize the Fund's institutional focus on structural issues?
- 52.** Do Directors agree that this helps provide a more strategic approach to selectively strengthen the Fund's macrostructural analytical work and tools?
- 53.** Do Directors agree with the forward-looking analytical agenda on structural reforms?
- 54.** Do Directors concur that labor markets and infrastructure are areas in which the Fund may need to scale up its expertise?
- 55.** Do Directors see merit in exploring options to enhance interagency cooperation and coordination, with the focus outlined above?

## Annex I. Recent Macrostructural Analytical Work at the Fund

This Annex presents selected recent analytical work by IMF staff on macro-relevant structural reforms and policy issues. It includes policy papers presented to the Executive Board, cross-cutting analytical work, as well as analysis done in the context of multilateral and bilateral surveillance.<sup>1</sup>

Table A. Fund Board Papers on Macrostructural Issues		
Reference/Title	Coverage	Reform or Policy Issue
<i>Current Challenges in Revenue Mobilization</i> (2015)	AM, EM, LIDC	Revenue administration
<i>Fiscal Policy and Long-term Growth</i> (2015)	AM, EM, LIDC	Fiscal structural reforms
<i>Making Public Investment More Efficient</i> (2015)	AM, EM, LIDC	Public investment
<i>Update on Fiscal Transparency Initiative</i> (2014)	AM, EM, LIDC	Fiscal transparency
<i>Spillovers in International Corporate Taxation Policy</i> (2014)	AM, EM, LIDC	Tax policy
<i>Fiscal Policy and Income Inequality</i> (2014)	AM, EM, LIDC	Fiscal redistribution
<i>Budget Institutions in G-20 Countries</i> (2014)	G-20	Budget institutions
<i>Long-Run Growth and Macroeconomic Stability in Low-Income Countries—The Role of Structural Transformation and Diversification</i> (2014)	LIDC	Export diversification; product market
<i>Jobs and Growth—Analytical and Operational Considerations for the Fund</i> (2013)	AM, EM, LIDC	Labor market
<i>Macroeconomic Policy Frameworks for Resource-Rich Developing Countries</i> (2012)	EM, LIDC	Fiscal structural reforms
<i>Fiscal Transparency, Accountability, and Risk</i> (2012)	AM, EM, LIDC	Fiscal transparency
<i>Fiscal Policy and Employment in Advanced and Emerging Economies</i> (2012)	AM, EM	Labor market
<i>Revenue Mobilization in Developing Countries</i> (2011)	LIDC	Tax policy
<i>The Challenge of Public Pension Reform in Advanced and Emerging Economies</i> (2011)	AM, EM	Pension
<i>Macro-fiscal Implications of Health Care Reforms in Advanced and Emerging Economies</i> (2010)	AM, EM	Health care

<sup>1</sup> Based on inputs provided by area and functional departments. Includes only documents already published. An expanded version of this list will be made available to staff as a step toward building a macrostructural toolkit for staff to facilitate sharing of expertise and country experiences.

## Annex II. Defining and Measuring Structural Reforms

The priority for this paper is to focus on reform indicators that cover a sufficiently large sample across all income groups to ensure that the analysis in this paper is sufficiently representative of the entire Fund membership. However, structural reforms are inherently difficult to measure because they often involve policies or conditions that cannot be easily quantified, particularly compared to the measurability of many macroeconomic policies. In this regard, it is important to acknowledge data constraints—both in availability, measurement, and coverage—that limit the scope for quantitative analysis of structural reforms.

While more exhaustive and granular indicators are more readily available for advanced economies, and in particular types of reforms, this underscores the importance of efforts underway to address data gaps, including by the Fund. Nevertheless, there have been a number of efforts to develop indicators that facilitate cross-country empirical analysis of structural reform, including work done by the IMF (2008) as well as other international organizations.

The database used for the analysis in this paper covers 108 countries—33 advanced markets (AMs), 53 emerging markets (EMs), and 22 low-income developing countries (LIDCs)—during the period 1970-2011. It includes data for 10 types of structural reforms compiled from a wide array of sources such as the Economist Intelligence Unit, Fraser Institute, IMF, and Organisation for Economic Cooperation and Development (OECD). The reform areas covered include financial sector reforms, trade liberalization, institutional reforms, as well as a range of reforms related to the functioning and regulation of markets. Following are the descriptions of the specific reform variables:

### Financial Sector Reforms

**Banking System Reform:** The banking sector reform index is a composite of five sub-indices on: (i) interest rate controls, such as floors or ceilings; (ii) credit controls, such as directed credit, and subsidized lending; (iii) restrictions on bank competition, such as limits on branches and barriers to entering the banking sector, including licensing requirements or limits on foreign banks; (iv) the degree of state ownership; and (v) the quality of banking supervision and regulation, including power of independence of bank supervisors, adoption of a Basel I capital adequacy ratio, and framework for bank inspections. Each of these sub-indices is aggregated with equal weights. *Source:* Prati et al. 2012 "Which reforms work and under what institutional environment? Evidence from a new dataset on structural reform", Abiad and others (2008).

**Capital Market Development:** The index refers to policies that either regulate or encourage the development of securities markets, including the auctioning of government securities, establishing debt and equity markets, policies to encourage the development of bond and equity markets, and on the openness of the domestic stock market to foreigner investors. *Source:* Abiad, Abdul, Enrica Detragiache, and Thierry Tressel, "A New Database of Financial Reforms," IMF Working Paper WP/08/266, December 2008.

## Trade Reform

**Trade Liberalization:** This index reflects average tariff rates, with missing values extrapolated using implicit weighted tariff rates. It is measured on a scale of 0 to 1, where zero means tariff rates are 60 percent or higher and 1 means tariff rates are zero. *Source:* Prati et al. 2012 "Which reforms work and under what institutional environment? Evidence from a new dataset on structural reform."

## Institutional Reform

**Legal System and Property Rights:** This index gauges the legal protections afforded individuals and property, and thus a legal system consistent with economic freedom in terms of the rule of law, security of property rights, an independent and unbiased judiciary, and an impartial court system. The index is assembled by EFW-Fraser Institute from three primary sources: the PRS Group's *International Country Risk Guide*, the World Economic Forum's *Global Competitiveness Report*, and the World Bank's *Doing Business* project and Worldwide Governance Indicators. *Source:* EFW-Fraser Institute Database, 1975–2012.

## Market Regulation and Function

**Agriculture:** This index aims to capture the extent of government intervention in the market for the main agricultural export commodity in each country. Each country-year pair is assigned one of four degrees of intervention: (i) maximum (public monopoly or monopsony in production, transportation, or marketing); (ii) high (administered prices); (iii) moderate (public ownership in relevant producers, concession requirements); and (iv) no intervention. *Source:* Prati et al. 2012 "Which reforms work and under what institutional environment? Evidence from a new dataset on structural reform"; IMF Index of Agricultural regulation.

### Business regulation:

- *Promotion of competition:* This is a qualitative indicator which looks at government policies on actively promoting competition and curbing unfair business practices. It is scored on a 1-5 scale as follows: (1) very poor-no effective competition institutions or legislation; (2) poor-competition policy and legislation exist; little enforcement action; (3) fair-some sanctions to curb monopoly power; reduction of entry restrictions; (4) good-significant actions to reduce monopoly power and promote competition; (5) very good-unrestricted entry to almost all markets. Effective enforcement of well-drafted competition policy. *Source:* Economist Intelligence Unit.
- *Policy environment for foreign investment:* This index scores countries between 1 and 10 on a variety of measures, including government policy towards foreign investment, investment protection schemes, and the risk of expropriation, with 1 being the worst and 10 the best. *Source:* Economist Intelligence Unit.

**Labor Market Reforms:**

- *Hiring and firing regulations:* This index is based on an Executive Opinion Survey conducted by the World Economic Forum, which asks whether the hiring and firing of workers in a country is impeded by regulations (=1) or flexibly determined by employers (=7). *Source:* World Economic Forum, Global Competitiveness Report.
- *Collective bargaining:* This index is based on an Executive Opinion Survey conducted by the World Economic Forum, which asks whether wages in a country are generally set by a centralized bargaining process (=1) or up to each individual company (=7). *Source:* World Economic Forum, Global Competitiveness Report.

**Regulation in energy, transport and communications (ETCR):** This index summarizes regulatory provisions in seven sectors: telecoms, electricity, gas, post, rail, air passenger transport, and road freight. In this regard, regulations pertain to factors such as market entry, public ownership, vertical integration, and market structure. *Source:* OECD.

**Infrastructure**

**Infrastructure:** While to date there is no established index that appropriately captures infrastructure reform, here we use public capital—the principal input into the production of public infrastructure—that is most commonly used in Fund and academic analysis. The PPP-adjusted (\$2005) public capital stock is measured as the accumulated value of public investment over time, adjusted for depreciation which varies by income group and over time. *Source:* Fiscal Monitor.

**Innovation**

**R&D Expenditure:** Current and capital expenditures (both public and private) on creative work undertaken to increase stock of knowledge, expressed as percent of GDP. *Source:* Economist Intelligence Unit.

## Annex III. Empirical Approach & Results

### I. Panel Regression Analysis

The regression analysis proceeds in three steps:

- **Step 1 – We estimate the relationship between different types of reform and productivity growth (Table 1, main text).** A separate panel regression equation is estimated for each country group using a sample of 108 countries—33 AMs, 53 EMs and 22 LIDCs—from 1970 to 2011.

$$\Delta \log(TFP_{i,t}) = \beta_0 + \beta_1 \log(TFP_{i,t-1}) + \beta_2 X_{i,t-1} + \mu_t + \nu_i + \varepsilon_{i,t} \quad (1)$$

$\Delta TFP_{i,t}$  denotes Total Factor Productivity (TFP) growth in country  $i$  at year  $t$ . Regressions are estimated using annual data.  $X_{i,t-1}$  is a one-year lag of each reform indicator. Various reform indices are considered one at a time (see definitions in Annex II). The equation controls for time effects  $\mu_t$  to capture common time trends, i.e. oil price shocks, and time-invariant country effects  $\nu_i$ , i.e. historical and legal origins.

- **Step 2 – We calculate and compare the productivity payoffs of different reforms within each country group (Table 3, main text).** As the correlation across reform indices does not allow for including all reforms simultaneously in the regression, we compare the yield from each reform by comparing the TFP growth impact of moving from the 25<sup>th</sup> percentile in each country group to the top performer or “frontier” in each group. We multiply the coefficient estimates of each reform,  $\beta_2$  with the distance to the top performer in that reform category.

$$TFP \text{ growth impact} = \beta_2 * \text{distance} ; \text{ where } \text{distance} = \overline{\text{reform}_{\text{top-performer}}} - \text{reform}_{i(25\text{thpercentile})} \quad (2)$$

- **Step 3 – We provide a relative ranking of the reforms with the highest productivity payoffs within each group.**

Tables 1 and 3 present the results of the Step 1 and 2 above, respectively. Results in Table 1 capture the differential effect of a certain type of reform on TFP growth. For example, the coefficient estimate on Infrastructure in EMs implies that a one standard deviation improvement in the index raises annual TFP growth in EMs by about 0.4 percentage points. As the high co-movement of reforms do not allow for using several reforms simultaneously in the regression, the estimates for each index obtained in Table 1 can be compared across country groups, but not across reform indices. To overcome this issue we multiply the regression coefficient estimate in Table 1 with the “room for reform” for countries in the group. Results in Table 3 capture the change in TFP growth from an improvement in an index from the 25<sup>th</sup> percentile to the top of the index for the given country group. For example, such an improvement in the infrastructure index for the EM group results in 3.8 percentage points increase in annual TFP growth. Some coefficient estimates (especially for AMs) drop out because countries have already reached the “frontier” of a reform index and therefore the reform gap is zero.

## II. Robustness of Panel Regression Analysis

We check the robustness of the baseline panel regression results along several dimensions. These include: (a) using longer lags of reforms indices (2 or 3 years); (b) including additional control variables—economy-wide level of education, institutional capacity, and terms of trade; (c) lagged dummy variable for systemic banking crises (Laeven and Valencia; 2012); and (d) using the sub-sample ranging from 1990–2011. We also examine the impacts of reforms on output and investment growth. The robustness results are summarized in Table A1. In the case of longer lags, most of the baseline results remain broadly unchanged up to a lag of 3 years. In the regressions with additional control variables, the coefficients for reform indices remain robust to the inclusion of measures of education and institutional capacity, and to a lesser extent the terms of trade.<sup>1</sup> The inclusion of lagged systemic banking crisis did not affect the baseline results, nor did the use of the 1990–2011 sub-sample data. We further conducted a joint test of coefficient equality between country groups that confirms that the baseline estimates are indeed statistically different from each other (at 1 percent significance level).

**Table A1: Robustness Check Results:  
Alternative Control Variables**

REFORMS	AM	EM	LIDC
<b>Financial Sector Reform</b>			
Banking system reform	C, D	A, B, C, D	A, B, C, D
Interest controls			A, C, D
Credit controls	B, C, D	B, C, D	A, B, C, D
Privatization		A, B, C, D	C, D
Supervision	A, C, D	A, B, C, D	A, B, C, D
Capital market development	A, C, D	B, C, D	B, C, D
<b>Trade Liberalization</b>			
Tariff rates (average)			A, B, C, D
<b>Institutional Reform</b>			
Legal system and property rights		A, B, C, D	B, C, D
<b>Infrastructure</b>			
Public capital stock	A, B, C, D	A, B, C, D	B, C, D
<b>Market Deregulation</b>			
Agriculture			B, C, D
Policy environment for foreign investment	A, B, C, D		
Promotion of competition		A, B, C, D	
Hiring and firing regulations	A, B, C, D	A, C, D	
Collective bargaining	A, B, C, D	B, C, D	
Energy/Transport/Communications	B, C, D		
<b>Innovation</b>			
R&D Spending	A, B, C, D		

Note: Robustness checks are based on the baseline only (see Table 1). Letters indicate significance of 15 percent or less when using (A) longer lags of reform indices; (B) additional control variables - education, institutional capacity, terms of trade; (C) systemic banking crisis dummy; and (D) a sub-sample over

Source: IMF staff estimates.

<sup>1</sup> The robustness check is conducted by adding one control variable at a time to the baseline equation. When the 3 control variables are added together, the results for regulation reform indices and banking system reform in AMs disappear.

Table A2 shows the results from our baseline specification, when using output and real investment growth as alternative dependent variables. The structure of the panel regression on the right-hand side remains the same as the baseline, except that we replace the lagged TFP level with the lagged GDP level. The results indicate significant and positive effects on real output growth for most reform types, particularly in EMs and LIDCs. Of the reform types, we found that financial sector reforms had universal significant impacts on output growth across all country groups. The results using investment growth, however, are weaker. Notably, reforms aimed at improving policy environment for foreign investment in AMs, and legal system/property rights and labor market regulations in EMs, were associated with positive and significant growth in investment.

Table A3 considers robustness to the baseline results presented in Table 3 (main text) by assessing the long-run (steady-state) TFP impact across different types of reforms in each

income group. The impact of a large reform is now assessed by multiplying the long-term marginal effect obtained by the composite coefficient estimate  $-\beta_2/\beta_1$  in the baseline specification (1) by the gap between the top performer and the bottom 25<sup>th</sup> percentile in each reform index. It is shown that reform priorities within each country group (AMs, EMs, LIDCs) are broadly similar to the baseline, with most of the top priority reforms remaining important by both short-run and long-run measures (reforms with unchanged relative priorities are indicated with a “\*”). A few notable exceptions—where reforms may have higher (“+”) or lower (“-”) impacts over the longer term—are as follows:

**Table A2: Robustness Check Results:

## STRUCTURAL REFORMS AND MACROECONOMIC PERFORMANCE

- For AMs and EMs, the size of the long-term TFP level effect associated with loosening of hiring and firing regulations does not stand out among other reform types, unlike its short-term TFP growth effect.
- On the other hand, decentralizing the collective bargaining process and improving the quality of banking supervision become more important for EMs in terms of the long-term level effect.
- For LIDCs, developing the capital market has a relatively moderate short-term growth effect, but its long-term level gain ranks among the highest across reforms.
- For all country groups, infrastructure investment generates the highest long-term TFP level gain across major reform areas.<sup>2</sup>

Source: IMF staff estimates.

<sup>2</sup> The interpretation of the long-run results warrants some caution as the concept of a *steady-state impact* of reform on level TFP becomes less clear in the context of our estimation approach, which assumes that the potential impact of reforms on countries' macro outcomes inherently depends on their level of development (AM, EM, LIDC).

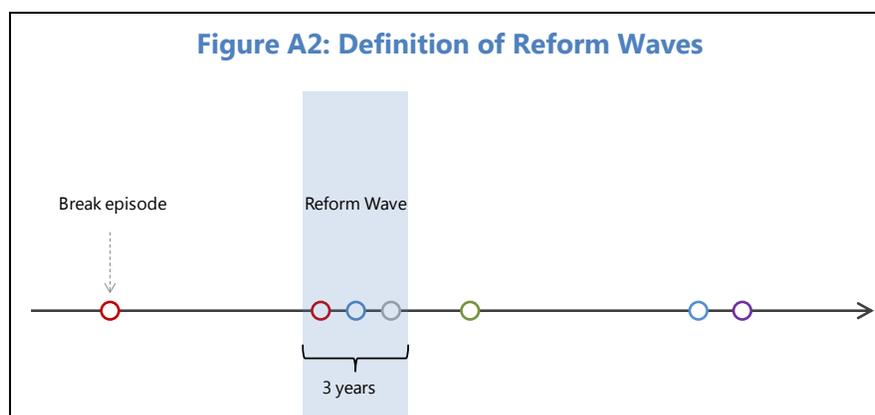

### III. Episodes Analysis

In this exercise, we first identify, for each reform variable, break points in time that lead to large and sustained improvements in a country (“reform episodes”). The time trends of these breaks, including the frequency and the composition of reform types both at the global and the country group level, are presented in Section III.B. The approach we adopt is a straightforward one, which essentially involves comparing, over a fixed window, the pre- and the post-break average TFP growth rates. It therefore establishes, as in the case of the regression analysis, association and not causation. The data (countries, reform variables) used are identical to the one from the regression analysis.

Specifically, we identify breaks using an intuitive heuristic method. Specifically, for each country  $i$ , we first calculate the 3-year differences of a reform variable  $X$  as follows:  $\Delta X_3^i = X_{t+3}^i - X_t^i$ . We then pool together these 3-year differences across the entire sample countries—AMs, EMs, and LIDCs—to form a single distribution for  $X$ . We define *breaks, or reform episodes*, as those that satisfy the following criteria: (a) the observation belongs to the top 3 percentile of the distribution (Figure A1); (b) the annual change over the 3 years following the observation is always positive; and (c) if there are two or more consecutive observations that meet (a) and (b), we pick the first observation as the break. These rules imply that, by construction, breaks would occur at most every 3 years in a country for each reform variable.

To examine the impacts of these multiple, simultaneous reforms, we define a “reform wave” as an incidence of 3 or more breaks in different areas over a 3-year period.

## STRUCTURAL REFORMS AND MACROECONOMIC PERFORMANCE

According to this definition, we identify a total of 34 reform waves—5 AMs, 23 EMs, and 6 LIDCs. These 34 reform waves accounted for 103 individual breaks—15 AMs, 70 EMs, and 18 LIDCs—or about 16 percent of the total 644 breaks identified from the break analysis.

Figure A3: Summary of Reform Waves

#### IV. Robustness of Episodes Analysis

This Annex describes several robustness exercises that were implemented to examine how well the baseline “episodes” analysis holds.

The baseline results broadly hold under different distribution thresholds. Applying 1 and 5 percent cut-off values results in total breaks of 227 and 984, respectively, roughly proportionate to the number of breaks from the baseline 3 percent threshold. Despite the substantial difference in the number of breaks, however, we found the positive correlation between reform breaks and productivity growth to hold across country groups and reform types with only a few exceptions. Furthermore, in many cases, the breaks that belong to the top 1 percent of the distribution—i.e. those with larger structural improvements—are associated with higher subsequent productivity growth increases.

Using different time windows to calculate post-break productivity gains leads to similar results. Specifically, we conducted tests with symmetric windows of 3, 4, 6 years around breaks, as well as an asymmetric window of 3-year pre-break and 5-year post-break. Notwithstanding a few exceptions, we find that the results from these tests are broadly consistent with the baseline, albeit at varying degrees depending on country groups and reform types.

Outliers among identified breaks also do not seem to matter much. To check this, we compare the 5-year *median* annual TFP growth rates before and after breaks (based on the 3 percent threshold), instead of averages. The baseline results still broadly hold in this case, except for financial sector supervision and collective bargaining for AMs and interest controls for LIDCs.

Finally, for relevant reforms, we find that about a half of our baseline breaks coincide with those identified using a standard statistical approach. We used as the method of reference, a modified version of Bai and Perron (1998, 2002) developed by Berg et al (2012) for small sample data. A break point identified using our heuristic approach “coincides” with one from the statistical method if the latter takes place within one year before or after the former. Based on this criterion, about 60, 40, and 50 percent of our baseline breaks coincide with those from the Berg et al (2012) method.

## Annex IV. Survey Methodology & Results

Staff conducted an online survey of IMF country mission chiefs in July 2015 to help gain insights into the macro-relevant structural reform needs of member countries.

### Survey Questions

- 1. The survey included several basic questions regarding country characteristics to facilitate analysis.** Mission chiefs were asked to specify each country's: region (e.g. Africa, Europe, etc.); income classification (advanced, emerging, or low-income); and other country characteristics (e.g., fragile state, small state, commodity exporter, etc.).
- 2. The survey also sought MCs' views on the macroeconomic importance of structural reforms.** The questions focused on 11 broad reform categories (plus scope to indicate other reform needs or priorities),<sup>1</sup> with MCs asked to indicate:
  - i. The extent to which each reform category is important for the country's macroeconomic performance;<sup>2</sup> and
  - ii. The top three structural reform priorities for the country's macroeconomic performance.

### Response Rate

- 3. Response rates were similar across income levels and regions, providing a representative assessment of the needs and views across the Fund's membership.** The overall response rate was around 60 percent, with rates ranging from 54 to 63 percent across income groups, and from 53 to 66 percent across regions.

Category of Countries	Number of Surveys Sent	Responses	
		Number	Rate
<b>Income Group:</b>			
<i>Advanced Economies</i>	35	19	54
<i>Emerging Markets</i>	87	55	63
<i>Low-Income Countries</i>	66	38	58
<b>Region:</b>			
<i>Africa</i>	45	24	53
<i>Asia and the Pacific</i>	35	21	60
<i>Europe</i>	43	26	60
<i>Middle East and Central Asia</i>	30	18	60
<i>Western Hemisphere</i>	35	23	66
<b>Overall</b>	<b>188</b>	<b>112</b>	<b>60</b>

<sup>1</sup> The reform categories included: banking sector; other financial and capital market, trade liberalization, legal system and property rights, infrastructure, agricultural, business regulations, labor market, industry regulations, technology and innovation, fiscal, and other reforms. The first 10 categories broadly parallel the reform indices used elsewhere in this paper (see Annex II), although survey responses may reflect somewhat different interpretations of these reforms.

<sup>2</sup> Four possible answers: to a great extent (weighted with a scoring of 3); to some extent (2); to a limited extent (1); and not at all/not applicable (0).

# The Role of Shocks and Institutions in the Rise of European Unemployment: The Aggregate Evidence.

Olivier Blanchard      Justin Wolfers \*

March 25, 1999

Figure 1 shows the evolution of unemployment in Europe since 1960. The figure plots average unemployment rates over 5-year intervals, starting in 1960, both for the OECD–Europe as a whole (the line) and for 15 individual OECD–Europe countries.<sup>1</sup> It shows the increase in the overall unemployment rate, from 1.7% in the early 1960s to 11.0% in the mid 1990s, together with the large dispersion in unemployment rates across countries, from 4.0% in Switzerland to more than 20% in Spain in the mid 1990s.

Explanations for these evolutions fall into three classes.

- Explanations that focus on the role of adverse economic shocks. Adverse shocks can indeed affect the natural rate; some of them may have permanent effects. And there are many plausible candidates for such shocks over the last 30 years. As unemployment started rising in the 1970s, the focus was on oil price increases and the TFP growth slowdown. Since then, the evolution of the real interest rate, and other shifts in labor demand have been added to the list.

Explanations based solely on shocks run however into a major empirical problem. Shocks can potentially explain the general increase in unemployment over time. But, as we shall see, they do not differ enough across countries to explain the cross-country variation so evident in Figure 1.

- Explanations that focus on the role of adverse labor market institutions. Most labor market institutions affect the nature of unemployment, and some can indeed potentially generate a high natural rate.

---

\*MIT and NBER, and Harvard. Harry Johnson lecture, April 1999. Preliminary. We thank Steve Nickell, Ed Lazear, John Addison and the OECD for data.

<sup>1</sup>The 8 time periods are 1960–1964 to 1990–1994, and 1995+ (typically 1995–1996.) The 15 countries included in OECD–Europe are Austria, Belgium, Denmark, Finland, France, Germany, Ireland, Italy, the Netherlands, Norway, Portugal, Spain, Sweden, Switzerland and the United Kingdom. Left out are Greece, Iceland and Luxembourg, for which we could not construct time series for all the explanatory variables used later in the paper.

With the persistence of high unemployment, explanations based on adverse institutions (“labor market rigidities”) have become steadily more popular. But explanations based solely on institutions also run into a major empirical problem: Many of these institutions were already present when unemployment was low (and similar across countries), and, while many became more employment-unfriendly in the 1970s, the movement since then has been largely in the opposite direction. Thus, while labor market institutions can potentially explain cross country differences today, they do not appear able to explain the general evolution of unemployment over time.

- Explanations that focus on the interaction of adverse shocks with adverse market institutions. In one form or another, these explanations all rely on the idea that the effects of a given shock on unemployment may be larger or longer lasting, depending on the specific labor market institutions. For example, the modern rendition of hysteresis theories goes like this: If labor market institutions lead to a labor market with lower flows and higher unemployment duration, the risk is higher that adverse shocks lead some workers to become disenfranchised, reducing the pressure of unemployment on wages, and slowing down the return to lower unemployment.

It is easy to see what makes this last class of explanations attractive. It has at least the potential to explain not only the increase in unemployment over time (through shocks), but also the heterogeneity of unemployment evolutions (through the interaction of the shocks with different labor market institutions).

In a companion paper ([2]), we took stock of the underlying alternative theories. We looked at whether and how different shocks, and different institutions, may affect equilibrium unemployment. We looked at the channels through which shocks and institutions might interact. This led us to argue in favor of the third class of explanations. In this paper, we look at the aggregate empirical evidence more formally, at the role of shocks, institutions, and interactions, in accounting for the evolution of European unemployment.

To do so, we look at the data through two panel data specifications. In the first, we assume unobservable but common shocks across countries. In the second, we construct and use country-specific time series for a number of shocks. In both specifications, we allow for an interaction between shocks and institutions: The effect of a given shock on unemployment is allowed to depend on the set of labor market institutions of the country.

We see the results as surprisingly (at least given our priors) good: Specifications that allow for shocks, institutions, and interactions can account both for much of the rise and much of the heterogeneity in the evolution of unemployment in Europe. The magnitude of the effects of the shocks on unemployment are plausible. The magnitude of the effects of institutions are equally so. And their interactions can explain much of the difference across countries.

These results notwithstanding, four caveats are in order. First, the results

are preliminary. In many cases, we do not have time series for institutions, and the series we have may not be very good. Second, the results are typically weaker when we allow for time-varying rather than time-invariant measures for institutions. Third, while the time dimension of the panel is too short to learn much about dynamics (we aggregate time in five-year intervals, and thus have at most 8 time observations), the dynamic effects of the observable shocks do not reflect the long run neutrality—or near long run neutrality—properties suggested by the theory. Last, the fact that the specifications fit the data does not prove that the (rather loosely specified) theories are right; just that they are not obviously inconsistent with the data.

We believe we are the first to analyze the panel data evidence looking simultaneously at shocks, institutions and interactions. But we build on a large number of previous studies. [3] were among the first to emphasize both shocks and institutions in the initial rise in unemployment. An empirical attempt to explain U.K unemployment as a result of shocks, institutions, and interactions was presented by [4] in their book on unemployment. Two recent studies are by [9] and by [7]. We differ mostly from Phelps by allowing for institutions, and for interactions. We differ mostly from Nickell by allowing for observable shocks, and by having a panel data dimension. Our results are partly consistent with those of Phelps with respect to shocks, and largely consistent with those of Nickell with respect to institutions.

## 1 The shocks

Three shocks appear to have played an important role in the increase in European unemployment. (This short declarative sentence conveys more certainty than is justified. Caveats follow.)

### The decline in TFP growth

Starting in the early 1970s, Europe suffered a large decrease in the underlying rate of total factor productivity (TFP) growth. This is shown in Figure 2. The two lines in Figure 2a give the evolution of the average rate of TFP growth for the 15 countries of OECD–Europe (E15 in what follows) and for the 5 largest European countries, France, Germany, Italy, Spain, and the United Kingdom (E5). To give a sense of the heterogeneity across countries, Figure 2b gives the evolution of TFP growth in each of the E5 countries. (Showing all 15 countries would clutter the figure but yield similar conclusions).<sup>2</sup> TFP growth which ran at close to 5% in the 1960s decreased to 3% in the first half of the 1970s,

---

<sup>2</sup>Details of construction and sources are given in the appendix. First, we construct the rate of TFP growth for each year and each country by computing the Solow residual for the business sector, and then dividing it by the labor share. Under the assumption of Harrod neutral technological progress—the assumption that allows for steady state growth—this is the right measure of technological progress, and gives the rate at which the economy can grow along the balanced growth path. We then take averages for each 5-year period. Finally, E5 and E15 are simple (unweighted) averages of TFP growth over countries.

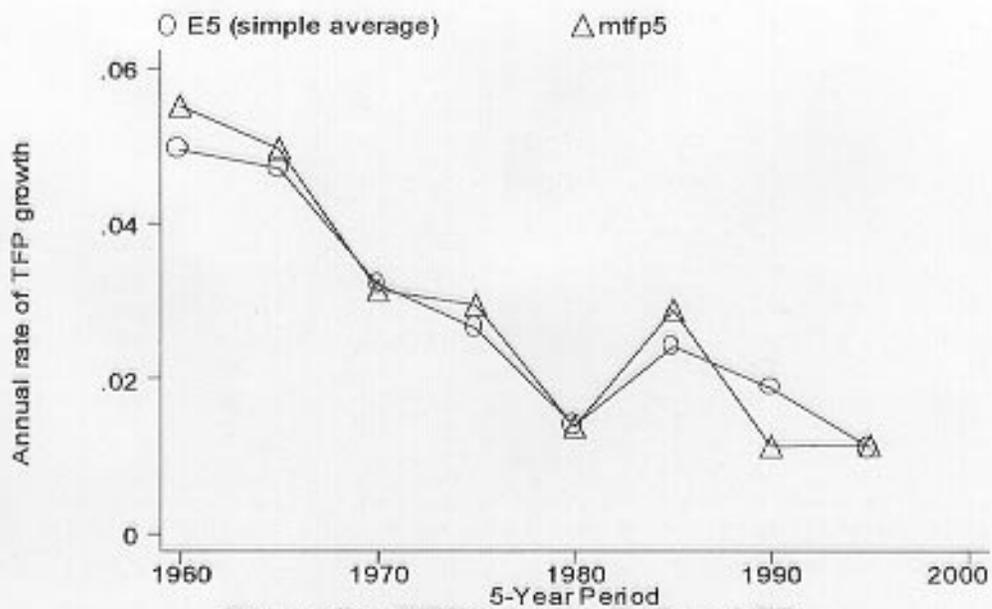

Figure 2a. TFP growth, E15 and E5

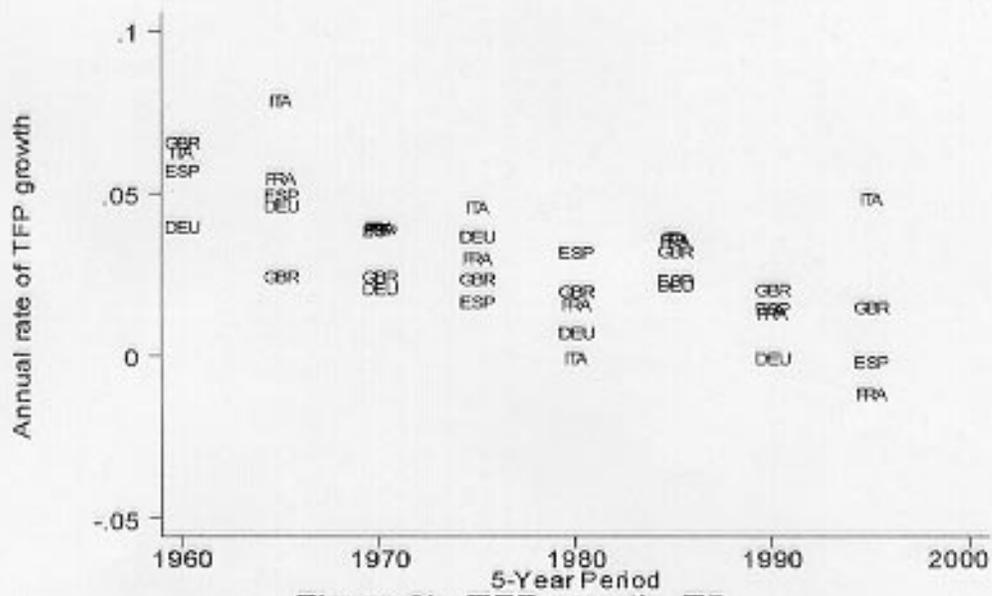

Figure 2b. TFP growth, E5

and to 2% in the second half of the 1970s. It has remained around 2% since then. The decline has affected countries in roughly similar fashion.<sup>3</sup>

This decrease in TFP growth was initially partially hidden by the large increase in the relative price of oil and other raw materials. Thus, much of the focus of the initial research (for example [3]) was on this increase in relative prices rather than on the slowdown in TFP growth. In retrospect, the slowdown in TFP growth was surely the more important shock.

There is no question that a slowdown in TFP growth can lead to higher equilibrium unemployment for some time. All that is needed is that it takes some time for workers and firms to adjust expectations to the new lower underlying rate, leading to wage growth in excess of productivity growth for some time. Can the effects of such a slowdown on unemployment be permanent? Theory suggests that the answer, to a first approximation, is no. Once expectations have adjusted, the effect on unemployment should mostly go away.<sup>4</sup> There lies the first puzzle of European unemployment. The initial shock is clearly identified. But, after more than twenty years, it is hard to believe that its effects are not largely gone. So, what accounts for today's high unemployment? There is much less agreement here, but two other shocks appear relevant.

### The real interest rate

Figure 3a gives the evolution of the average real interest rate for both the E15 and the E5. Figure 3b gives the real interest rate for each of the E5 countries.<sup>5</sup>

Figure 3 shows that, both for the E15 and the E5 countries, the real rate turned from positive in the 1960s to sharply negative in the second half of the 1970s, and then to large and positive in the 1980s and the 1990s. For some countries, the decline in the 1970s was nearly as dramatic as the ensuing increase. Figure 3b shows how the real rate in Spain went down from 2% in the 1960s to -5% in the mid 1970s, back to 5% in the 1980s and the 1990s. For others, such as Germany, the real rate has remained much more stable.

Why might such changes in the real interest rate affect the equilibrium unemployment rate? Because they are likely to affect capital accumulation, and at a given wage (and thus a given ratio of employment to capital), to shift labor demand.<sup>6</sup> Are the effects on unemployment likely to be permanent? Theory is largely agnostic here. Again, a plausible answer is that long run effects, if present, are likely to be small.

<sup>3</sup>Note that, in contrast to the other observations which are based on five yearly observations, the observation for 1995 is typically based on only one (1995) or two (1995 and 1996) years. Thus, one year can make a lot of difference. This is the case for Italy in this figure.

<sup>4</sup>We shall use the existence of the companion paper as an excuse for keeping our discussion of theoretical issues, and of relevant references, to a minimum.

<sup>5</sup>First, we compute the real interest rate for each year and each country as the nominal long rate on government bonds minus a five-year average of lagged inflation. We then take averages for each 5-year period. E15 and E5 are computed as simple (unweighted) averages across countries.

<sup>6</sup>This is not the only channel, but we believe it is the main one. For more discussion, see the companion paper.

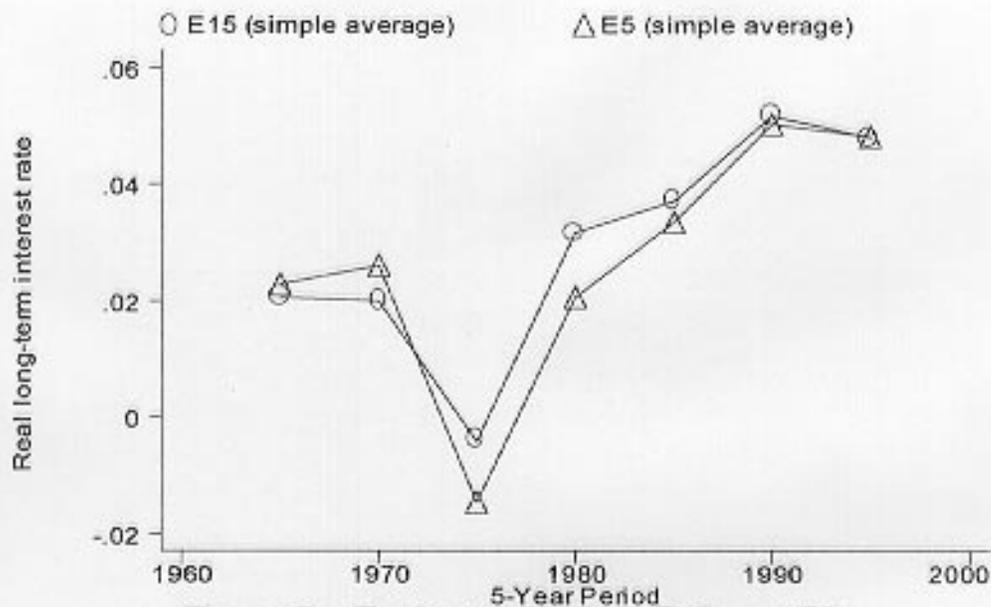

Figure 3a. Real interest rate, E15 and E5

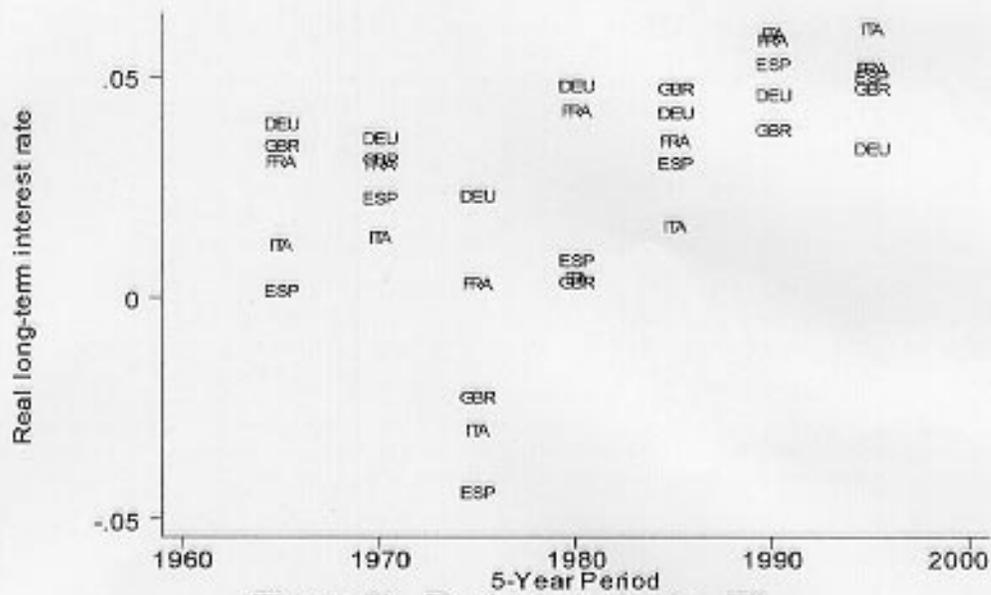

Figure 3b. Real interest rate, E5

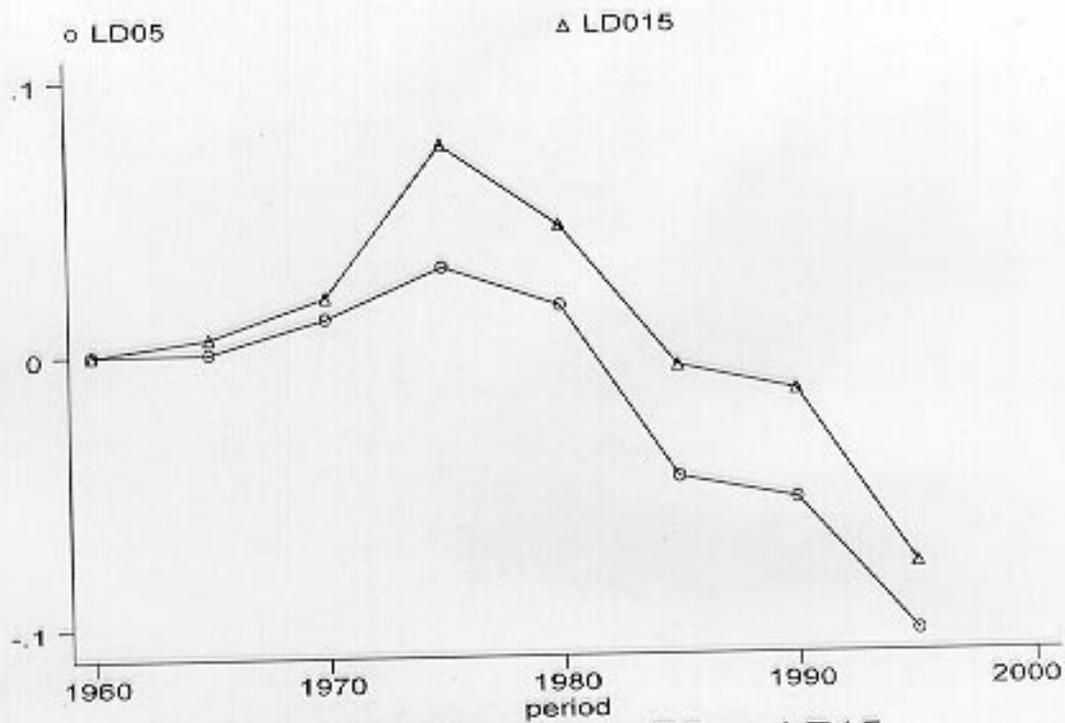

Figure 4. Log labor share, E5 and E15

It is clear from Figure 3 that the pattern of interest rates may help explain why unemployment kept increasing in the 1980s, even as the effects of lower TFP growth on unemployment were—presumably—declining. This suggests that, had real interest rates been stable, unemployment would have been higher in the 1970s, and lower in the 1980s. Put another way, the low real interest rates of the 1970s delayed some of the increase in unemployment by a decade or so. The higher real interest rates since the early 1980s may help explain why unemployment has remained high in the 1980s and the 1990s.

### Shifts in labor demand

Figure 4 gives the evolution of the log of the labor share for both the E15 and the E5 (normalized to equal zero in 1960). For both groups of countries, the evolution of the share is quite striking. After increasing in the 1970s, the share started decreasing in 1980s and the decline has continued since then. For the E5, the labor share is now 10% lower than it was in 1960; for the E15, it is 8% lower.

Why look at the evolution of the labor share? Suppose that technology was characterized by a Cobb Douglas production function, both in the short and the long run. The decrease in the share since the 1980s would then reflect either technological bias away from labor—a decrease in the coefficient on labor in the production function— or a decrease in the wage relative to the marginal product of labor. In either case, the implication would be an adverse shift in labor demand.<sup>7</sup>

The elasticity of substitution may be equal to one in the long run, but it is surely less than one in the short run. In that case, movements in the share will also reflect the dynamic response of factor proportions to factor prices. Indeed, much of the increase in the labor share in the 1970s surely reflects the effects of the increase in the real wage relative to TFP growth together with a low short-run elasticity of substitution, and some of the decrease since then reflects the adjustment of proportions over time. In [1], we argued however that more has been at work than the adjustment of factor proportions to factor prices, and that the large decline in the share reflects a genuine adverse shift in labor demand.

We shall use the measure of the shift in labor demand constructed in that earlier paper; this measure can be thought as the log of the labor share, purged of the effects of factor prices on the share in the presence of a low elasticity of substitution in the short run. Figure 5a plots the evolution of this measure of the labor demand shift for both the E5 and the E15. Figure 5b plots the evolution of the measure for each of the E5 countries. Both figures show how the adjustment eliminates much of the increase and subsequent unwinding in

---

<sup>7</sup>Let  $Y = N^\alpha K^{1-\alpha}$ . Let the ratio of the wage to the marginal product of labor  $w/Y_n \equiv \mu$ .  $\mu$  is equal to 1 under perfect competition in both goods and labor markets, but may differ from 1 otherwise. Then the share of labor  $\alpha = a\mu$ . A decrease in  $\alpha$  reflects a decrease in  $a$  or a decrease in  $\mu$ . Also labor demand can be written as  $\log N = \log Y - \log w + \log \alpha$ . A decrease in  $\log \alpha$  leads to an equal decrease in  $\log N$  given output and the wage. This is why we look at the log share.

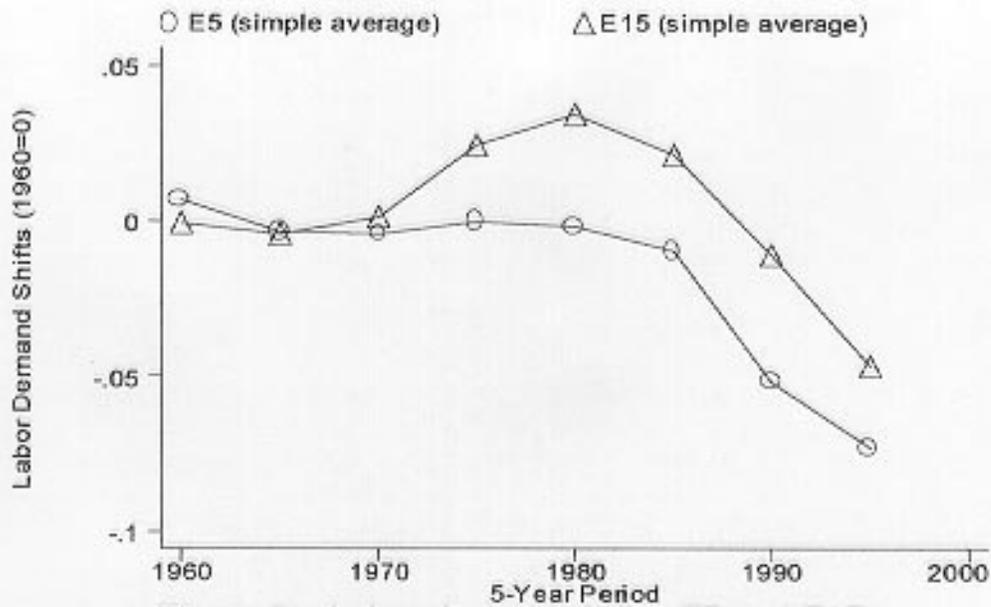

Figure 5a. Labor demand shifts, E5 and E15

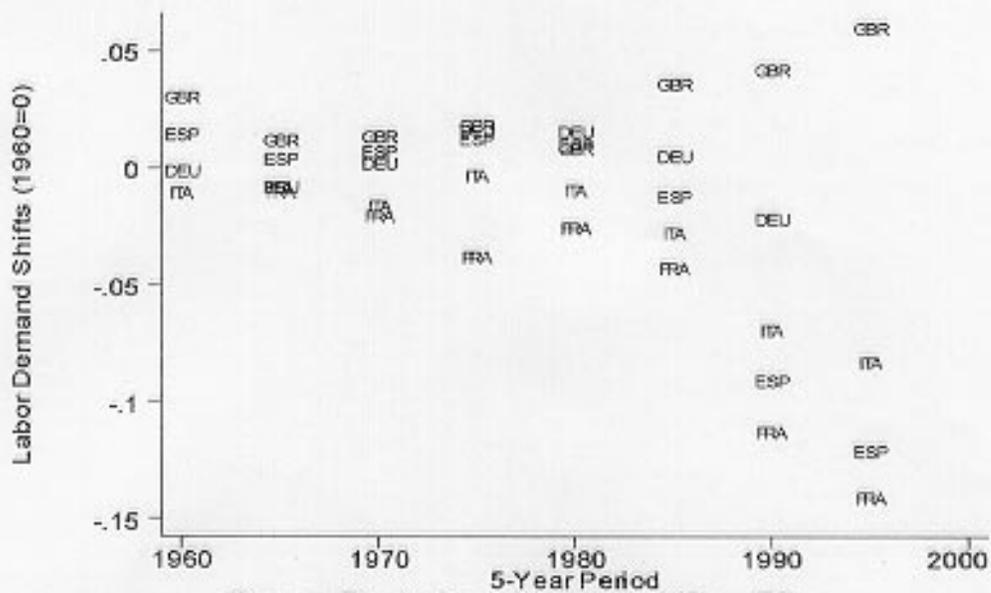

Figure 5b. Labor demand shifts, E5

the share in the 1970s (visible in Figure 4). Figure 5a shows little movement in the measure until the mid 1980s, with a strong decrease thereafter. Figure 5b shows the sharp difference between the UK where, if anything the shift has been positive (the underlying labor share has remained roughly constant) and countries such as Spain or France (where the adverse shift has exceeded 10%).<sup>8</sup>

Such an adverse shift in labor demand can clearly lead to higher equilibrium unemployment for some time. Its dynamic effects however are quite different from those of the two shocks we looked at earlier. Think for example of the shift as coming from a decrease in labor hoarding by firms—one of the interpretations suggested in [1]. As firms get rid of redundant workers, the result will be a decrease in employment, and so an increase in unemployment. Thus, such a shift has the potential to explain why unemployment has remained high in many countries in the 1990s. But the decrease in labor hoarding also leads to higher profit, which in turn should lead, over time, to capital accumulation and higher employment. This is a relevant point to keep in mind when we think about the future. If it is the case that such a shift is indeed responsible for some of the unemployment of the 1990s, then this suggests a brighter future, as the favorable effects start dominating and lead to an increase in employment over time.

#### **Equilibrium versus actual unemployment**

We have focused so far on factors that affect equilibrium unemployment. There is no question however that part of the evolution of unemployment in Europe comes from the deviation of actual unemployment from equilibrium unemployment.

In environments of low to medium inflation, the change in inflation is likely to be a good signal of where equilibrium unemployment is relative to actual unemployment. Decreasing inflation is likely to reflect an unemployment rate above the equilibrium rate; increasing inflation reflects the reverse. Figure 6a shows the evolution of the change in inflation for the E5 and the E15. Figure 6b shows the evolution of the change in inflation for each of the E5.<sup>9</sup> The change in inflation was positive in the 1970s, suggesting an actual unemployment rate below the equilibrium rate. The change in inflation has been negative since then, suggesting that the equilibrium rate has been lower than the actual rate. In other words, macroeconomic policy probably delayed some of the increase in unemployment from the 1970s to the 1980s. And, as inflation is still slowly declining, actual unemployment probably exceeds equilibrium unemployment at this point. By how much is difficult to say: the relation between the change in inflation and the deviation of unemployment from its equilibrium may well be different at very low inflation.

Two caveats are in order as we end this section. First, what we have taken as

---

<sup>8</sup>This distinction between Anglo-Saxon and Continental countries was one of the issues taken up in [1].

<sup>9</sup>First, we construct the change in inflation (using the business sector GDP deflator) for each year and each country. We then take the average for each 5-year period. The variables for E5 and E15 are simple (unweighted) averages.

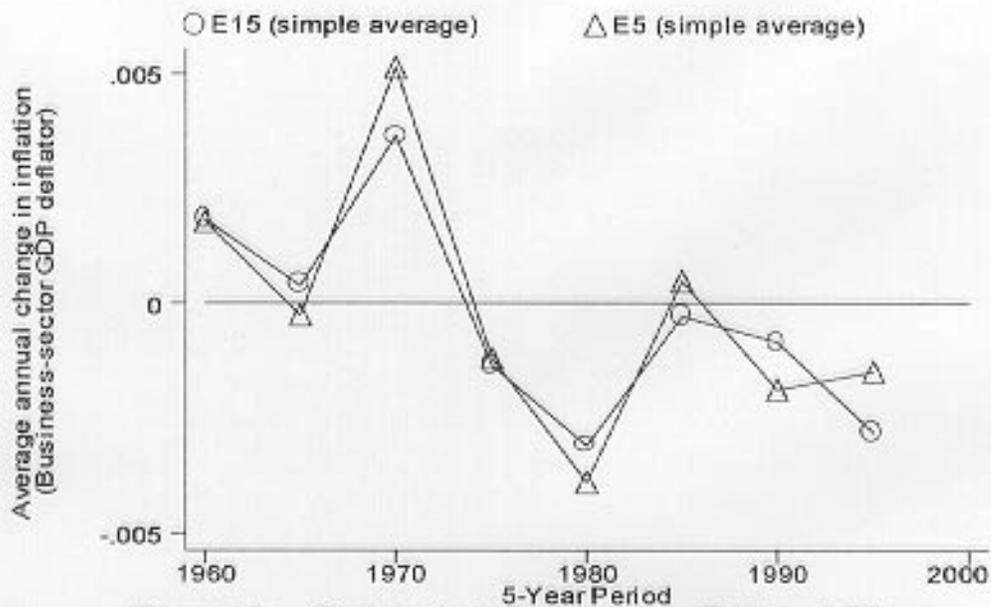

Figure 6a. Change in inflation rate, E15 and E5

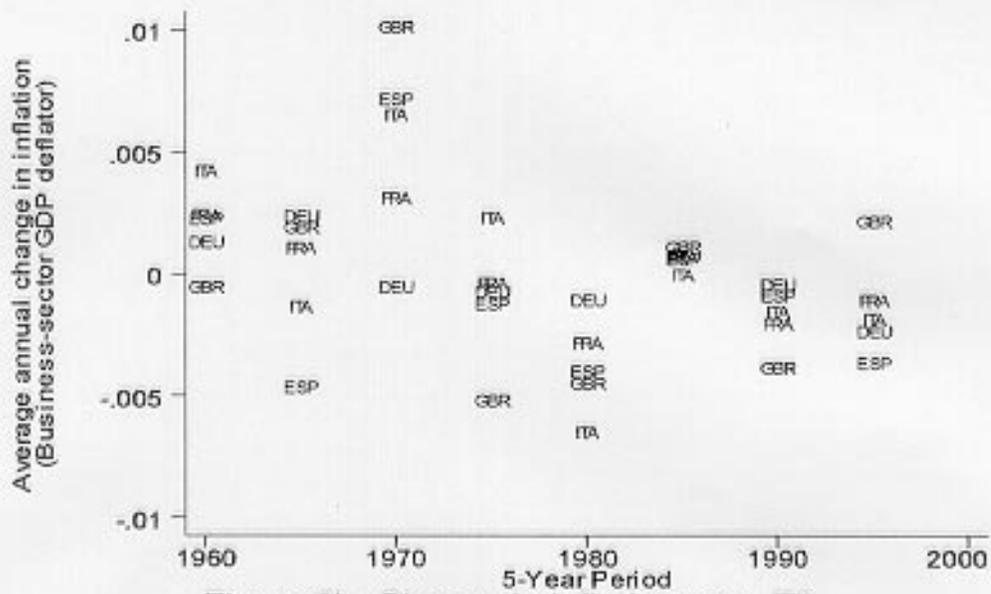

Figure 6b. Change in inflation rate, E5

“shocks” are at best proximate causes, and should be traced to deeper causes. This is particularly clear for interest rates and labor demand shifts. Second, there may well be other shocks. The notion that economic turbulence has increased is attractive; the effects of changes in turbulence on unemployment are likely to depend on labor market institutions. But the evidence of increased turbulence—at least measured by various indexes of reallocation across sectors, skills or regions—is surprisingly weak. Shifts in relative labor demand for skilled and unskilled may also have played a role in the rise of aggregate unemployment; the evidence is still unclear on this as well.<sup>10</sup>

Yet, this section suggests the following story: Europe was hit with major adverse shocks in the 1970s, oil price increases, but also, and more importantly, a large slowdown in TFP growth. Unemployment increased, but the adverse impact was initially softened both by lower real interest rates and a macroeconomic policy leading to less of an increase in actual than in equilibrium unemployment. As the effect of the adverse shocks of the 1970s receded, higher interest rates and tight macroeconomic policy contributed to higher equilibrium and actual unemployment in the 1980s. Finally, adverse labor demand shifts can potentially account for why unemployment has remained high in the 1990s.

## 2 The institutions

While in the 1970s the discussion of the rise of unemployment focused primarily on shocks (oil prices, TFP growth slowdown, then later, tight money), the persistence of high unemployment for another two decades has led to a shift in focus from shocks to labor market institutions. Indeed, many discussions of European unemployment ignore shocks altogether, and focus exclusively on “labor market rigidities”. What typically follows is a long list of so called “rigidities,” from strong unions, to high payroll taxes, to minimum wages, to generous unemployment insurance, to high employment protection, and so on.

We have learned however from theory that things are more complicated. Some of the so-called rigidities may represent rough institutional corrections for other distortions in the labor market. Some institutions may be bad for productivity, for output, and for welfare, but may not lead to an increase in unemployment. A short summary of the large literature—a literature largely triggered by the rise in European unemployment—goes as follows:<sup>11</sup>

- Some labor market institutions increase the equilibrium unemployment rate. First among them is the unemployment insurance system. More generous insurance increases unemployment through two separate channels: The first, and the focus of most microeconomic empirical work, is

---

<sup>10</sup>These issues are discussed at more length in our companion paper.

<sup>11</sup>A longer discussion is given in our companion paper. A very useful and wider ranging presentation of both theory and facts is given by [8] in their chapter for the forthcoming Handbook of Labor Economics. A primarily theoretical discussion is given by [6] in their chapter for the forthcoming Handbook of Macroeconomics.

lower search intensity. The second is the effect on the bargained wage at a given rate of unemployment.

The specifics of unemployment insurance matter, not only for the unemployment rate, but its composition. For a given overall level of generosity, more backloaded benefits (a longer period during which benefits are paid) lead to a larger proportion of long-term unemployed in the pool of unemployed. This aspect is relevant in thinking about interactions of shocks and unemployment insurance.

- Some labor market institutions change the nature of unemployment, but have an ambiguous effect on the equilibrium unemployment rate. Among them is employment protection. Employment protection both decreases the flows of workers through the labor market, and increases the duration of unemployment. This makes for a more stagnant labor market, with a higher proportion of long-term unemployed, again an aspect relevant to interactions of shocks and employment protection. But the effect of lower flows and higher duration on the natural rate itself is definitely ambiguous.
- Some labor market institutions may not have much effect either on the rate or the nature of unemployment. Their incidence may be mainly on the wage, not on unemployment. This is the case for many of the components of the so called “tax wedge.” To a first approximation, what matters here is how taxes affect the ratio of after-tax unemployment benefits to after-tax wages. Taxes which by their nature apply equally on the unemployed and the employed, such as consumption or income taxes, are likely to be roughly neutral. And, if the unemployment insurance system tries to achieve a stable relation of unemployment benefits to after-tax wages—a reasonable assumption—even payroll taxes may not matter very much.

Turning to the evidence, the two relevant questions are: How much do labor market institutions vary across countries? And how have they evolved over time? Thanks to work by the OECD and by a number of researchers, we have fairly good answers to the first question. Evidence on the second remains more limited.

For the state of the answers to the first question, we refer the reader to [7] and [8]. In much of what we do later, we shall use the data set for institutions put together by Nickell and described in those two papers. We limit ourselves to a few observations here.

To give a sense of the variations in measures of institutions both across countries and across measures, Figure 7 focuses on two institutions, unemployment insurance and employment protection. It plots four scatter diagrams. In each case, the unemployment rate for each country is the average unemployment rate for the period 1990-1994, roughly the period corresponding to the Nickell measures for institutions.

- The two diagrams on top show the relation of the unemployment rate to

two alternative measures of the replacement rate—the ratio of unemployment benefits to the wage).

The measure on the left is the average value over 1990-1994 of the OECD measure. The OECD has constructed such a measure for each country, every two years, going back to 1961. The measure is an unweighted average of the replacement rate for different categories of workers, different family situations, and different durations of unemployment. The measure on the right is from Nickell and Layard.

Together, the two figures suggest three conclusions: (1) There is substantial variation in the degree of unemployment insurance across countries. (2) The two measures give far from identical rankings (the  $R^2$  of a regression of the OECD measure on the Nickell measure is 0.69) (3) The bivariate relation of either of the two measures to the unemployment rate is weak.

- The bottom two diagrams do the same exercise for employment protection.

The figure on the left uses the OECD employment protection index for the late 1980s. The index is a weighted average of cardinal measures along four dimensions of employment protection—procedural inconvenience, severance and notice period, treatment of unfair dismissals, and regulation of fixed-term contracts and temporary employment. The figure on the right uses the Nickell measure, which is itself taken from the OECD Jobs Study, and is an average of a number of ordinal rankings by the OECD and other researchers. Roughly the same three conclusions apply: variation across countries, across the two measures, and a poor relation to unemployment.

Let's now turn to the second question, the evolution of institutions over time. The basic question is a simple one. Have European labor market institutions become steadily worse since the early 1970s; or do they in fact date back much further, to a time when unemployment was still low? The question is simple, but the answer is not.

Time series for at least part of the period and a subset of countries have been put together for some institutions—unionization, the tax wedge—by the OECD and other researchers.<sup>12</sup> We shall limit our discussion here to two institutions, unemployment insurance, and employment protection.

- Figure 8a gives the evolution of the OECD measure of the replacement rate, for each 5-year period, for each of the E5 countries. (Presenting it for the E15 leads to too crowded a picture, but the same conclusions.)

The figure shows different evolutions across the E5. In Germany, France, and the UK, the replacement rate was relatively high to start; it has increased a bit in France, decreased a bit in Germany, more so in the UK.

In Spain and Italy, the replacement rate was very low at the start. It

---

<sup>12</sup>See for example the CEP LSE data base.

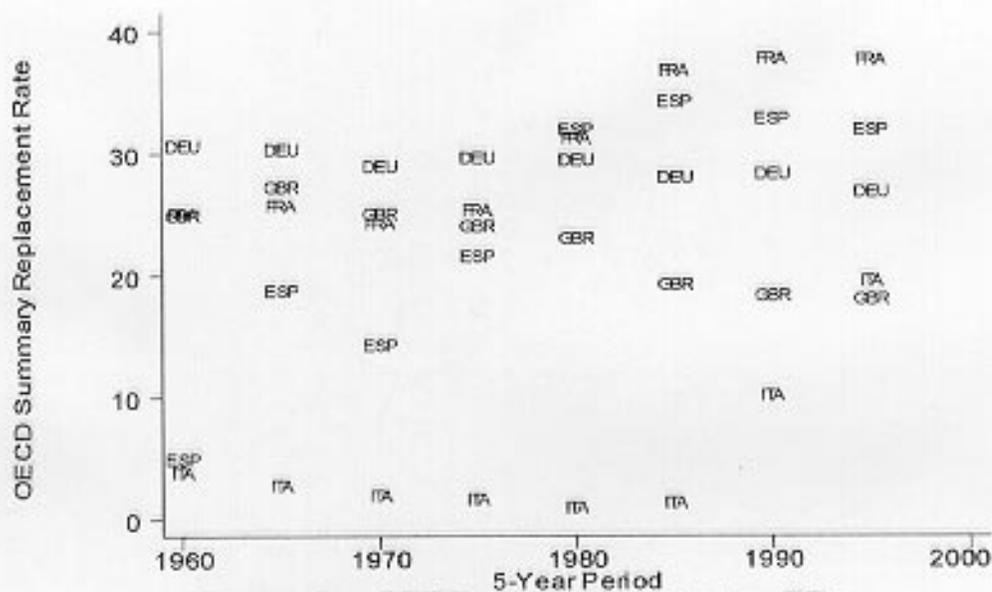

Figure 8a. OECD replacement rate, E5

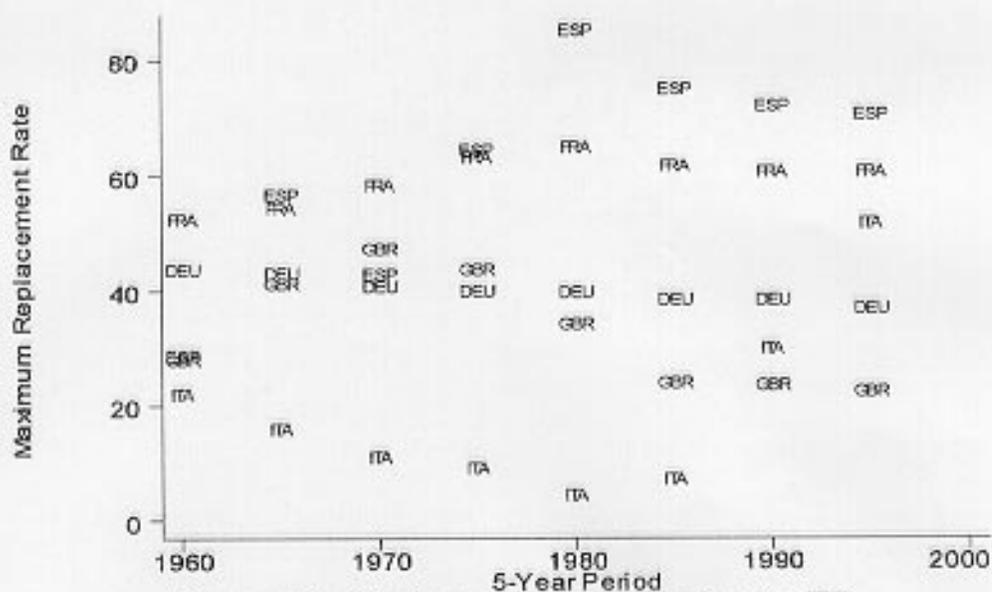

Figure 8b. Maximum replacement rate, E5

increased in the 1960s in Spain, and only more recently in Italy. Both are now at levels comparable to other countries. In short, there is no simple common answer.

The OECD measure is a summary measure of the replacement rate, and in some ways, not a very attractive one. It gives equal weight to the replacement rate in year 1, to the average replacement rate in years 2 and 3, and to the average replacement rate for years 4 and 5; but given the exit rate from unemployment, the generosity of benefits in years 4 and 5 for example is clearly less important for the determination of unemployment than the generosity of unemployment in year 1. Also, a system which gives 100% replacement to half of the workers and 0% to others will have very different effects from one that gives 50% replacement to all (i.e the effects are likely to be non linear), and so on. An indication of the relevance of this complexity is shown in Figure 8b. Figure 8b plots the maximum replacement rate over all categories and all durations of unemployment for each country and each subperiod. What clearly comes out is how this rate increased until the late 1970s, and how it has decreased since then. In other words, some of the excesses have been eliminated. This may be more important than changes in the average replacement rate.

- Putting together series on employment protection is difficult. We have taken a stab at it by constructing series based on published and unpublished data from the OECD, as well as on earlier work by [5]. Details are given in the appendix. There is a number of reasons why these series are at best rough approximations to the evolution of employment protection. In particular, the OECD data, which we use to construct the measures from 1985 on, are based on a much broader set of dimensions of employment protection than the Lazear series (notice period and severance pay for a blue collar worker with ten years seniority) which we use to construct the series before 1985.

This caveat notwithstanding, Figure 9 shows the evolution of the employment protection index for the E5 countries since 1960. (Again, the figure for the E15 would be harder to read, but yield similar conclusions). Note again the diversity of evolutions, and the lack of a simple answer.

Spain and Italy appear to have had high employment protection throughout. Employment protection in Spain was high under Franco, before unemployment increased.<sup>13</sup> In both countries, employment protection has decreased since the mid 1980s—in Spain, largely because of the development of fixed term contracts rather than the weakening of protection for workers on indefinite contracts. In France and Germany, employment protection was low to start with, then increased in the late 1960s and early 1970s, and has been stable since then.<sup>14</sup>

---

<sup>13</sup>In Italy, de facto employment protection was exceptionally high in the early 1970s, something not reflected in the Lazear measure, and by implication not reflected in our measure.

<sup>14</sup>Informal evidence suggests that employment protection was high in France even in the

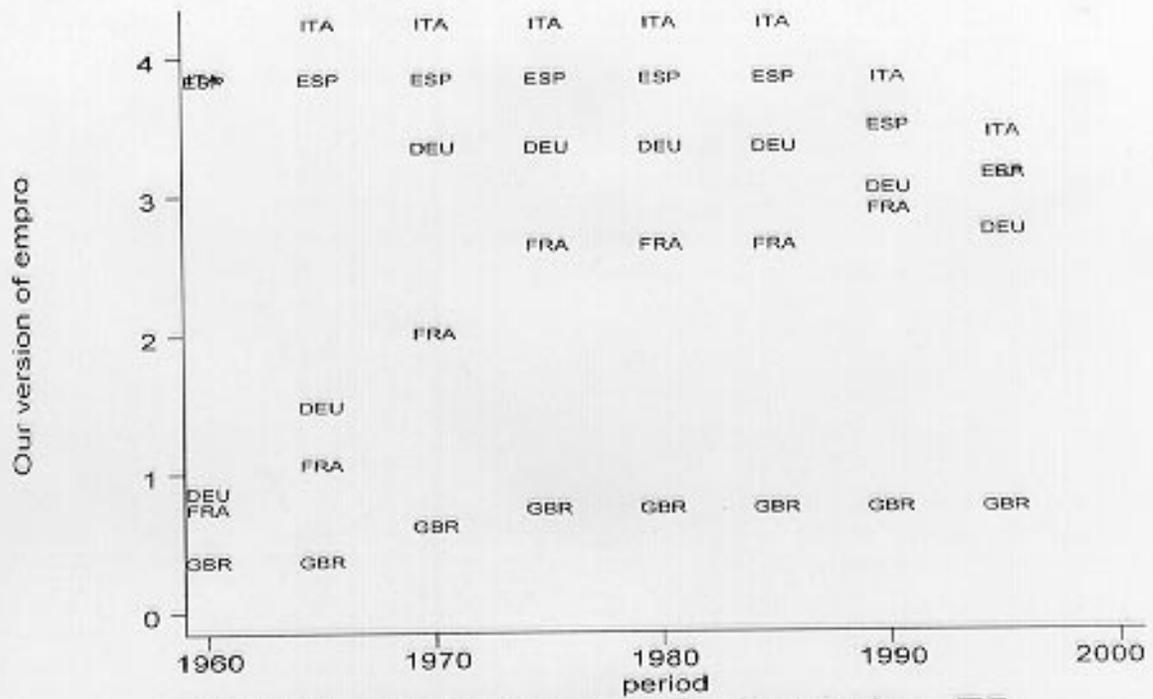

Figure 9. Employment protection index, E5

To conclude: There is enough heterogeneity in labor market institutions within Europe to potentially explain differences in unemployment today. As to the evolution of institutions over time: It is clear that neither the view that labor market institutions have been stable through time, nor the view that labor market rigidities are a recent development are right. Some countries have had these institutions for a long time, others have acquired them more recently. There clearly was an increase in employment-unfriendly institutions in the late 1960s and early 1970s. Since then, there appears to have been a small but steady decline.

### 3 Time effects and interactions

In looking more formally at the data, we proceed in two steps. In this section, we treat shocks as unobservable but common across countries. In the next, we treat shocks as observable and country specific.

To make it easier to relate our results to the existing literature, our first specification in this section relies on the set of time invariant measures for institutions used by [7].<sup>15</sup> The specification is the following:

$$u_{it} = c_i + d_t \left( 1 + \sum_j X_{ij} b_j \right) + e_{it} \quad (1)$$

where  $i$  is a country index,  $t$  a (5-year) period index, and  $j$  an institution index. The dependent variable,  $u_{it}$ , is the unemployment rate in country  $i$  in period  $t$ .  $c_i$  is the country effect for country  $i$ .  $d_t$  is the time effect for period  $t$ .  $X_{ij}$  is the value of institution  $j$  in country  $i$  (in this first specification, we do not allow for time variation in institutions, so there is no index  $t$ .) The specification allows for the effects of the common time effects on unemployment to depend on the specific set of labor market institutions of a country. This dependence is captured by the parameters  $b_j$ .

We estimate this equation using data from 20 countries—the same set of countries as Nickell: The E15 countries listed and examined earlier, plus the United States, Canada, New Zealand, Australia and Japan. (These countries are clearly important controls for any story about European unemployment). There seems to be little point in looking at year-to-year movements in institutions or in shocks (we shall introduce time varying institutions later in this section, and time varying observable shocks in the next) unless one allows for a generous lag structure, and this would take us too far. So, as in earlier figures, we divide time in 8 five-year periods, from 1960–65 to 1995+.

Following Nickell, we use measures for eight “labor market institutions” (a brief description of the eight measures is given in the appendix, but the reader is referred to [7] for more details):

---

1960s. Again, this is not reflected in the Lazear measure, and by implication, not reflected in our measure either. This may be an issue for other countries as well.

<sup>15</sup>Nickell gives values for these institutions for both 1983-1988, and 1989-1994. We use the average.

- Three of them measure aspects of the social treatment of unemployment: the replacement rate (RR), the number of years over which unemployment benefits are paid (Ben), and a measure of active labor market policies (ALMP).
- One is a measure of employment protection (EP).
- One is a measure of the tax wedge (Tax). And the last three measure aspects of collective bargaining: union contract coverage (Cov), union density (Den), and (union and employer) coordination of bargaining (Coor).

The specification of equation (1) is clearly more a description of the data than the outcome of a tightly specified theory of interactions. Let us take up two issues here:

First, many of the models emphasizing interactions suggest that the main effect of labor market institutions may be to affect the persistence of the effects of shocks on unemployment, rather than their magnitude—as captured in (1) (see again our companion paper for a discussion and references). Given the short time series dimension of the data, introducing interaction dynamics in (1) would be unwise. And, when looking at five-year averages, more persistence translates into a stronger average effect of the shock over the five-year period.

Second, one might argue against the introduction of country effects altogether. If one believes that all differences in the average level of unemployment across countries are due to the eight institutions listed above, one can replace the country dummies by the set of institutions and estimate their effect on the level of unemployment. We shall show the results of such a specification below (the conclusions remain largely the same); but we do not find it a plausible assumption and do not use this as our benchmark.

Equation (1) is estimated by non-linear least squares. The results of estimation are presented in Table 1. All the measures of labor market institutions are defined so that an increase in the measure is expected to increase the effect of an adverse shock on unemployment: the expected sign of each  $b_j$  is positive.<sup>16</sup> Also all measures of institutions are constructed as deviations from the cross country mean; this way the time effects gives the evolution of unemployment for a country with mean values of all 8 institutions.

The results of Table 1 are surprisingly strong (relative to our priors). The estimated equation gives the following description of the data:

- Estimated time effects account for an increase in the unemployment rate equal to 7.2%. That is, the equation implies that, if a country had had mean values for all eight institutions, its unemployment rate would have grown by 7.2% over the period.

---

<sup>16</sup>Thus, we multiply the original Nickell measures of active labor market policies and of coordination by  $-1$ . We take the expected effect of employment protection to be that more employment protection leads to a larger effect of adverse shocks on unemployment, and the expected effect of coordination that more coordination reduces the effects of adverse shocks on unemployment

Table 1. Time effects interacted with fixed institutions.

	(1) Coefficients	(2) Range of independent variable		(3) Implied range of effect of shock (mean = 1)	
Time effects *	7.2%				
Replacement rate	0.017 (4.9)	-40.0	30.0	0.32	1.51
Benefit length	0.202 (4.7)	-2.0	1.6	0.60	1.32
Active labor policy	0.017 (2.9)	-47.0	9.5	0.30	1.16
Employment protection	0.044 (3.0)	-9.5	9.5	0.68	1.32
Tax wedge	0.018 (3.1)	-17.0	22.0	0.71	1.37
Union coverage	0.101 (0.5)	-1.7	0.3	0.83	1.03
Union density	0.008 (2.0)	-30.0	39.5	0.76	1.32
Coordination	0.299 (5.1)	-2.0	2.0	0.40	1.60
Country effects	yes				
$\bar{R}^2$	0.948				

\*: Time effects: Estimated time effect for 1995+ minus estimated time effect for 1960-1965. Column (1): regression results, *t*-statistics in parentheses.

- Coefficients on all 8 institutions have the predicted sign. All are significant, except for the union coverage variable. The two most statistically significant variables are the replacement rate and the duration of benefits.

To give a sense of magnitudes, column (2) gives the range for each institutional measure (recall that these are deviations from the cross country mean). Column (3) then shows the effect of a given shock for the lowest and highest value of the corresponding institution. The way to read the column is as follows. Take three countries, all with mean values for institutions except one—say, employment protection in line 5. Take an adverse shock which has an effect of 1 on unemployment in the country with the mean value of employment protection. Then the same shock will have an effect of only 0.68 in the country with the lowest employment protection, but an effect of 1.32 in the country with the highest employment protection. The conclusion one should draw from column (3) is, given the existing variation in labor market institutions, the range of the effects of institutions on the impact of a given shock on unemployment is roughly similar across institutions.

- Not only are the coefficients plausible, but the model does a good job of explaining the differential evolution of unemployment rates across countries. Figure 10 plots the change in the fitted unemployment rate from 1965-70 to 1995+. The fit is quite good. Interactions between common shocks and different institutions can account for much of the actual difference in the evolution of unemployment rates across countries. (Recall that a pure time effect model with no interactions would predict no variation in predicted unemployment rates across countries: all the points would lie on a horizontal line.)

In short, equation (1) gives a surprisingly good description of the heterogeneity of unemployment evolutions as the result of common shocks interacting with different institutions. These results are indeed consistent with the two cross sections estimated by Nickell, and show that his results are robust both to the use of a longer time period and the introduction of country effects.<sup>17</sup>

One must worry however that these results are in part the result of economic Darwinism. The measures used by Nickell have all been constructed ex-post facto, by researchers who were not unaware of unemployment developments. When constructing a measure of employment protection for Spain, it is hard to forget that unemployment in Spain is very high... Also, given the complexity in measuring institutions, measures which do well in explaining unemployment have survived better than those that did not. Thus, in the rest of the section, we look at robustness, both vis a vis alternative specifications, and vis a vis the use of alternative—including time varying—measures of institutions.

---

<sup>17</sup>There are however some differences between estimated coefficients. In particular: Employment protection is significant here, not in Nickell. Union coverage is not significant here, but is significant in Nickell.

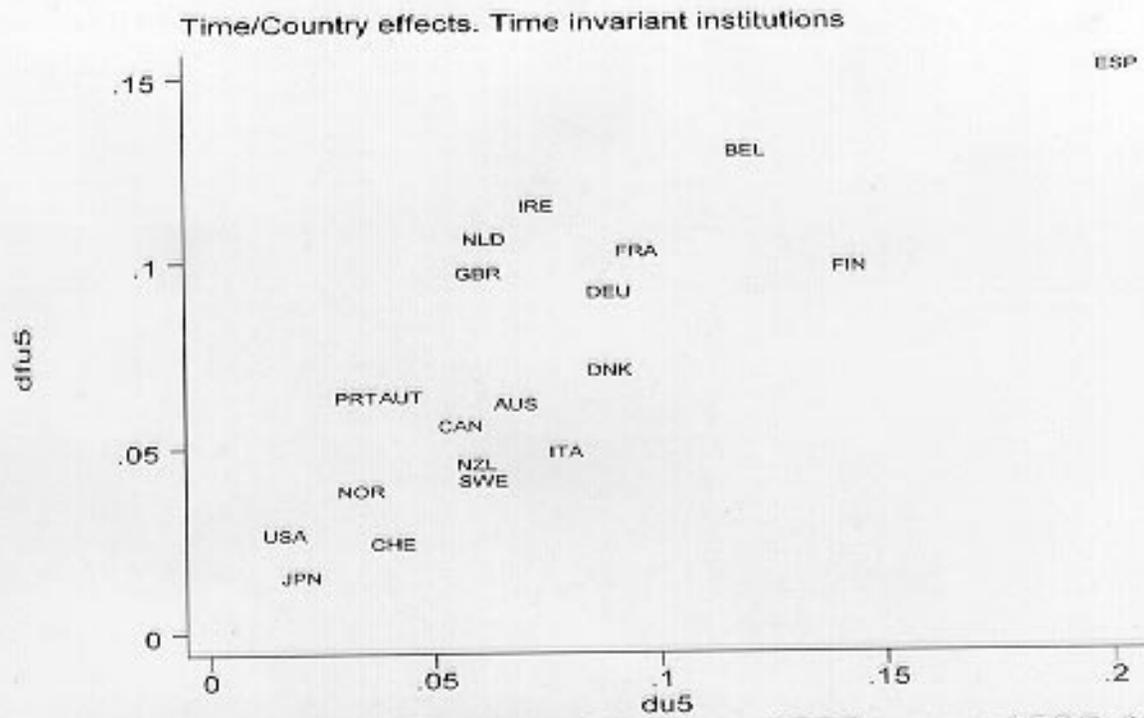

Figure 10. Actual and Predicted Delta  $u$ ; 1995+ over 1965-1970

Table 2 looks at alternative specifications. First, to give a sense of bivariate rather than multivariate relations, column (1) reports the results of 8 separate regressions, each regression allowing interactions with only one of the 8 measures for institutions. When introduced on their own, three measures are highly significant: the length of benefits, the degree of employment protection, and the degree of union coverage (which is insignificant in the multivariate specification). In contrast, the replacement rate, which is highly significant in the multivariate specification, is insignificant when introduced alone.

Column (2) reports the results of a single multivariate regression, replacing country effects by the levels of the institutional variables. That is, it imposes the constraint that all differences in unemployment levels be explained by differences in institutions. Only the coefficients on interactions are reported in column (2). They are roughly the same as in Table 1. The coefficients on the levels are typically insignificant. The fit is substantially worse than in Table 1.

Columns (3) and (4) present an attempt to adjust unemployment for deviations of actual from equilibrium unemployment. We start from the assumption that the following relation holds between the change in inflation, the actual and the equilibrium rate of unemployment:

$$\Delta\pi_{it} = -a(u_{it} - u_{it}^*)$$

We then construct “equilibrium unemployment” as  $u_{it}^* = u_{it} + (1/a)\Delta\pi_{it}$ ;  $1/a$  is often called the sacrifice ratio. Estimates of  $a$  for Europe for annual data typically range from 0.25 to 0.50.<sup>18</sup> Column (3) constructs  $u^*$  using a sacrifice ratio of 2.0; column (4) does the same using a ratio of 4.0.<sup>19</sup> Not much happens. The coefficients are very similar to those in Table 1;  $\bar{R}^2$  is slightly lower.

Table 3 looks at the implications of using alternative measures for some of the institutions.<sup>20</sup> Columns (1) and (2) look at alternative measures for replacement rates. Columns (3) and (4) look at alternative measures for employment protection.

Using the OECD database on replacement rates for each country since 1961, we construct an alternative set of two measures of the generosity of unemployment insurance. The first measure, RR1, is the replacement rate during the first year of unemployment averaged over all categories. The second, RR25, is the replacement rate during years 2 to 5 of unemployment, averaged over all categories and over all four years.

Column (1) shows the results of estimation using time invariant values for RR1 and RR25. For comparisons with the results using Nickell’s measures which apply to the late 1980s and early 1990s, we use the mean value of the two replacement rates for the period 1985–1990. Measures for the other 6 institutions

<sup>18</sup>If our approach to measuring the equilibrium unemployment rate is right however, then most existing estimates of  $a$ , which rely on a much rougher measure of equilibrium unemployment, are not right. We did not take up the task of estimating  $a$  in this paper.

<sup>19</sup>In doing so, we are implicitly assuming that the sacrifice ratio is not related to institutions. This is probably incorrect.

<sup>20</sup>This is the work in progress part of the paper.

Table 2. Time effects interacted with fixed institutions. Alternative specifications.

	(1)	(2)	(3)	(4)
	Institutions entered individually	No Country effects	$u^*$ sacrifice ratio=2.0	$u^*$ sacrifice ratio=4.0
Time effects		9.2%	6.6%	6.0%
RR	0.004 (1.0)	0.017 (4.1)	0.018 (4.7)	0.019 (3.8)
Ben	0.267 (5.8)	0.213 (4.1)	0.240 (4.9)	0.276 (4.3)
ALMP	0.007 (1.1)	0.017 (2.3)	0.020 (3.0)	0.025 (2.9)
EP	0.041 (3.5)	0.050 (2.8)	0.040 (2.5)	0.035 (1.7)
Tax	0.012 (2.0)	0.017 (2.4)	0.018 (2.9)	0.019 (2.4)
Cov	0.512 (4.2)	0.050 (0.2)	0.124 (0.6)	0.139 (0.5)
Dens	-0.002 (-0.4)	0.009 (1.8)	0.008 (1.7)	0.008 (1.4)
Coor	0.045 (0.8)	0.300 (4.2)	0.320 (4.3)	0.344 (4.0)
CE	yes	no	yes	yes
$\bar{R}^2$		0.923	0.942	0.912

Column (1): each coefficient is estimated using a different regression, allowing interactions between the time effects and the specific institution variable. Column (2): Values of institutional measures entered, but coefficients not reported. Columns (3) and (4): The dependent variable is equilibrium unemployment,  $u = 1/a\Delta\pi$ , where  $1/a$ , the sacrifice ratio, is 2 in column 3, 4 in column 4.

are the same as in Table 1. The fit is a bit worse than in Table 1. The two replacement rates are both individually significant, and jointly highly significant. Other coefficients are often less significant. In particular, the coefficient on employment protection is smaller, and less significant.

Column (2) shows the results of estimation using time-varying measures for RR1 and RR25. Relative to column (1), the fit, measured by the  $\bar{R}^2$  is only marginally improved. The part of the increase in unemployment due to time effects decreases from 7.2% to 6.2%: Some of the increase in unemployment is now explained by the increase in replacement rates. Other coefficients are largely the same as in column (1).

Columns (3) and (4) use the index of employment protection discussed in Section 2. In contrast to the Nickell index, which is a ranking of countries and thus ranges from 1 to 20, this index is a cardinal index, ranging theoretically from 0 to 6, empirically from 0 to about 4. Thus, in comparing coefficients to those obtained using the Nickell specification, keep in mind that the coefficients should be roughly 5 times larger to generate the same effect on unemployment.

Column (3) shows the results of estimation using time-invariant values of the index, equal to its value for 1985-1990. (The index for this time period is more reliable than for earlier periods— when we have to combine different sources to construct the index.) The results are very similar to Table 1.  $\bar{R}^2$  is a little higher. The effect of employment protection is similar in magnitude to that in Table 1 (i.e the coefficient is about 5 times larger), and highly significant.

Finally, column (4) shows the results of estimation using the time varying values of the employment protection index. Allowing for time variation does not improve the results. The part of the increase in unemployment accounted for by time effects increases to 8%.  $\bar{R}^2$  is slightly lower. The coefficient on the employment protection index decreases by nearly half and becomes less significant. These results can be read in three ways, and we do not yet have a strong view as to which one is right. First, the effects of employment protection are in fact less strong than suggested by previous regressions using time-invariant measures. Two, the series we have constructed are not very reliable; as we discussed in Section 2, we are worried about the evolution of the index early on. Three, the results come from reverse causality. Under this interpretation, the rise in unemployment has led over time to more employment protection, which is why there is a close relation between employment protection at the end of the sample and unemployment. But employment protection has little effect on unemployment, which is why the relation is weaker when using time series. Given the lack of strong evidence about the presence of a strong and reliable feedback from unemployment to institutions, we are skeptical; but we cannot exclude this interpretation.

To summarize the results of this section, a model with common unobservable shocks and interactions with institutions provides a good description of the evolution of unemployment rates across time and countries. The description appears reasonably robust—although less so with respect to time variation in institutions. This conclusion leaves open the issue of what these shocks might have been, and whether they have indeed been similar across countries. For this

Table 3. Time effects interacted with institutions. Alternative measures

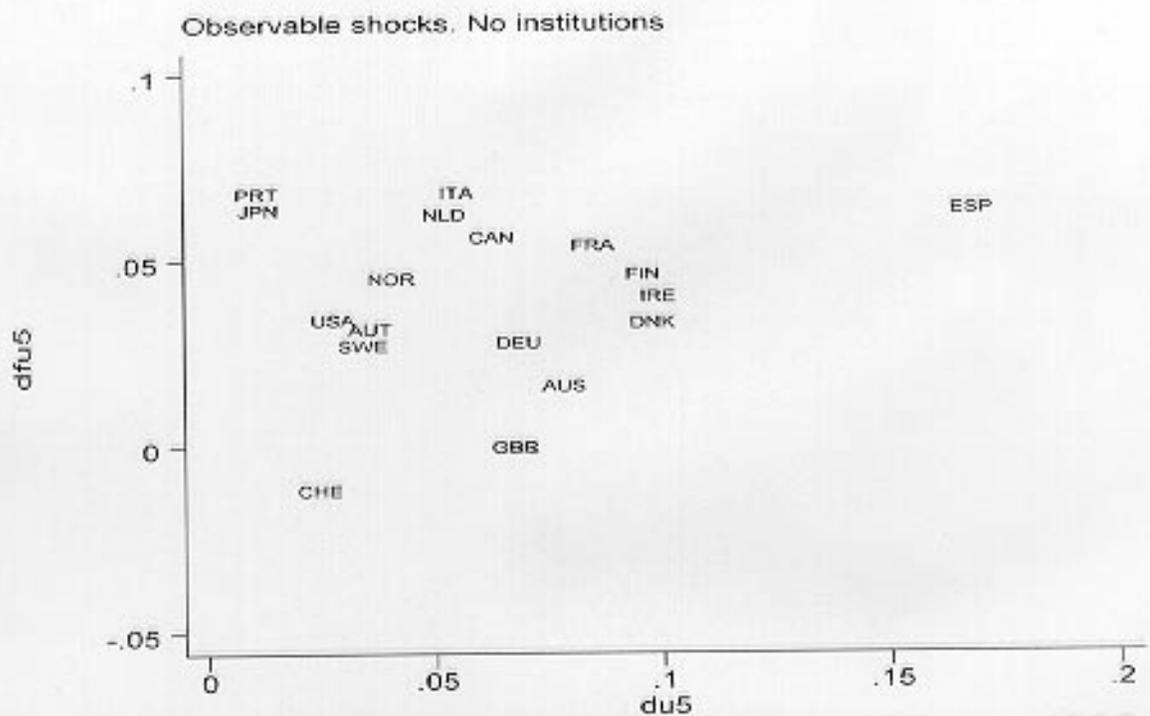

Figure 11. Actual and Predicted Delta u 1990-1995 over 1965-1970

reason, we now turn to a specification based on observable shocks.

## 4 Observable shocks and interactions

The benchmark specification we use in this section is the following:

$$u_{it} = c_i + \left( \sum_k Y_{kit} a_k \right) \left( 1 + \sum_j X_{ij} b_j \right) + e_{it} \quad (2)$$

where the notation is the same as before, but the unobservable common shocks of section 3 are now replaced by a set of country specific shocks;  $Y_{kit}$  denotes shock  $k$  for country  $i$  in period  $t$ .<sup>21</sup> (Again, our benchmark relies on time invariant measures of institutions, thus the lack of an index  $t$  for  $X$ . Later on, we look at results allowing for time variation for institutions.)

Following the discussion in Section 2, we consider three variables for the shocks and construct them for each country and each period. They are the rate of TFP growth, the real rate of interest, and the labor demand shift measure, respectively. We enter them as levels, but, given the presence of country dummies in the regression, they can be thought of as deviations from country averages— or from 1960 values. To make it easy to read the tables, each shock variable is measured so an increase is expected to increase unemployment initially; therefore the original measure of TFP growth is multiplied by  $-1$ . Due to some missing data for some countries, the panel is (slightly) unbalanced. Also, one observation requires special treatment. As discussed in [1], the Portuguese revolution was associated with a large permanent increase in the measured labor share (20% of GDP)—without a corresponding increase in unemployment. While this evolution is interesting in its own right, we decided to eliminate this effect by allowing for a dummy for Portugal, from 1960 to 1975.<sup>22</sup>

The natural first question is: Ignoring differences in institutions, how much of the evolutions of unemployment across time and countries can be explained using these three shocks? The answer is given in Table 4 and in Figure 11.

Table 4 presents regressions of the unemployment rate on the three shocks, leaving institutions out. Column 1 allows only for current values of the three shocks (recall however that each period is a five-year period). Each of the three shocks is significant, and the magnitudes of the coefficients are interesting. A decrease in TFP growth of 3 percentage points, as has happened in many countries, translates into an increase in the unemployment rate of 1.3%. An increase in the real interest rate of 5 percentage points leads to an increase in the unemployment rate of 3%. A decrease in the adjusted labor share of 10%, such as happened in France and in Spain since the mid 1980s, leads to

<sup>21</sup>Most theories predict that the interaction of institutions and shocks may be different for different shocks. But allowing for different interactions between each shock and each institution struck us as asking too much from our limited data set (which in this section, given data limitations, includes between 130 and 140 data points, depending on the specification).

<sup>22</sup>The difference between macro and labor panel data regressions is that, in macro, each data point is intimately known by the researcher...

Table 4. Shocks only.

Dependent var	(1) u (no lags)	(2) u (current and lagged)	(3) u* sacrifice ratio=2.0	(4) u* sacrifice ratio=4.0
TFP growth	0.43 (2.8)	0.36 (1.9)	0.32 (2.3)	0.22 (1.5)
lagged		0.67 (4.5)		
Real rate	0.61 (5.1)	0.42 (3.8)	0.61 (5.4)	0.60 (5.2)
lagged		-0.00 (0.0)		
LD shift	0.18 (2.4)	0.24 (2.4)	0.17 (2.4)	0.16 (2.2)
lagged		-0.05 (-0.7)		
CE	yes	yes	yes	yes
$\bar{R}^2$	0.583	0.706	0.673	0.576

an increase in the unemployment rate of about 2%. So, these shocks appear indeed to explain part of the evolution of the unemployment rate across time and countries.

Do differences in the magnitude of shocks easily explain the cross country heterogeneity in unemployment increases? The answer is no; this is shown in Figure 11. The figure plots the change in fitted unemployment against the change in actual unemployment from 1965-1970 to 1990-1995 (this is the longest time span for which data are available for all countries.). The relation is positive, but poor. The Netherlands and Spain have the same predicted increase in unemployment, yet very different outcomes. In short, the heterogeneity of shocks cannot account for much of the heterogeneity of unemployment evolutions.

The other columns in Table 4 explore variations of column (1). Column 2 allows for lags of each of the three variables. (Allowing for lagged unemployment with in effect 7 data points in the time dimension would be unwise). Both current and lagged TFP growth are significant. While theory suggests that the effects may build up for some time —as higher wages relative to TFP lead to low profit, and lower capital accumulation, it also suggests that the effects should eventually go away. There is no evidence of this in column 2. Only effects of the current real interest rate are significant; this sheds some doubt on the notion that the real interest rate works through capital accumulation and labor demand and suggests that some of the effects work through aggregate demand and the deviation of actual from equilibrium unemployment. The effects of the LD shift conform to the theory, positive initially, negative later. Columns 3 and 4 replace actual by equilibrium unemployment, constructed as in the previous section, for two values of the sacrifice ratio, 2.0 and 4.0. The fit in column (3) is better than in column (1) —but the dependent variable is not the same—; the effects of each of the three variables are similar.

Table 5 presents the results of the specification that allows for both shocks and interactions with institutions. Column (1) presents the results from estimating the benchmark specification (2).

The three variables measuring shocks are again very significant (more so than in Table 4). The effect of TFP growth is larger than in Table 4, the effects of the real interest rate slightly smaller.

Coefficients on 7 of 8 institutions have the expected sign. Only union coverage is negative, but insignificant. The most significant coefficients are on the replacement rate and the length of benefits. Except for union coverage, the pattern of coefficients is the same as in Table 1 (estimated with unobservable shocks), up to a factor of proportionality greater than 1. That is, they are in general 1.5 to 2 times larger than in Table 1. The mechanical explanation is that the observable shocks explain less of the general increase in unemployment, and the interactions must therefore explain more. The  $\bar{R}^2$  is much lower than in Table 1: despite the fact that they may differ across countries, observable shocks do not do as good a job as the set of 8 time effects in Table 1.

The specification does a good job of explaining differences in unemployment evolutions across countries. This is shown in Figure 12, which plots the change in fitted unemployment against the change in actual unemployment, from 1965-

## Shocks interacted with institutions

period

Figure 13. Actual and Predicted Unemployment Rates, by country

1970 to 1990-1995. The fit is quite good; clearly much better than in Figure 11, if not quite as good as in Figure 10. Figure 13 gives another way of looking at fit, by plotting the actual and fitted unemployment rate for each of the 20 countries over time. The visual impression is one of a good fit in nearly all cases (to facilitate comparison across countries the vertical scale is the same across countries. This unfortunately makes it harder to see the fit in each country.)

Column (2) looks at the effects of entering institutions one at a time. The conclusions are largely similar to those in the previous section. In particular, union coverage is very significant on its own, but not in combination with other institutions. Column (3) replaces actual by equilibrium unemployment, assuming a sacrifice ratio of 2.0. The fit is better, but the results are otherwise very similar.

Table 6 looks at alternative measures of institutions. Its structure is the same as for Table 3. Columns (1) and (2) look at the effects of using the two measures of replacement rates using OECD data. Column (1) uses a time invariant value equal to the average for 1985-1990; column (2) uses the time series. Columns (3) and (4) do the same, for employment protection. The table suggests two conclusions, both worrisome: Replacing the Nickell measures by alternative, but time invariant measures, substantially decreases the  $\bar{R}^2$ . Going from the time invariant to the time varying measures further decreases the fit. The coefficients on institutions remain consistently positive, but are typically smaller than in Table 5, and less significant. These results lead to the same discussion as in Section 3: Luck, or data mining, when the standard set of measures is used? Poor time series for institutions, interacting here with the fact that we are looking at their product with time varying and also imperfectly measured shocks? Or reverse causality (although the fact that the deterioration of fit happens when replacing one time invariant measure by another is not supportive of this hypothesis).

The conclusion we draw from the results in this section is that one can indeed give a good account of the evolution of unemployment across countries and times by relying on observable shocks and interactions with labor market institutions. There are clearly reasons to worry: The dynamic effects of shocks are not obviously consistent with the theory; the results are weaker when using time varying institutions. But, again, the results strike us as surprisingly good overall.

## 5 Conclusions

We have shown that an account of the evolution of unemployment based on the interaction of shocks and institutions does a good statistical job of fitting the evolution of unemployment both over time and across countries.

If this account is correct, one can be mildly optimistic about the future of European unemployment. The effects of some of the adverse shocks should go away. The real interest rate is likely to be lower in the future than in the recent past. The dynamic effects of what we have identified as adverse labor

demand shifts should eventually prove favorable to employment. Institutions are also slowly becoming employment-friendly. Further improvements should help reduce unemployment—although the poor results obtained using time-varying institutions make us reluctant to push this proposition strongly, at least based on the evidence in this paper.

## Abstract

We introduce a new data set on hiring and firing restrictions for 21 OECD countries for the period 1984–1990. The data are based on surveys of business people in the countries covered, so the indices we use are subjective in nature. Controlling for country and time fixed effects, and using dynamic panel data techniques, we find evidence that increasing the flexibility of the labor market increases both the employment rate and the rate of participation in the labor force. A conservative estimate suggests that if France were to make its labor markets as flexible as those in the US, its employment rate would increase 1.6 percentage points, or 14% of the employment gap between the two countries. The estimated effects are larger in the female than in the male labor market, although both groups seem to have similar long-run coefficients. There is also some evidence that more flexibility leads to lower unemployment rates and to lower rates of long-term unemployment. We also find evidence consistent with the hypothesis that inflexible labor markets produce “jobless recoveries” and introduce more unemployment persistence.

## 1. Introduction

One of the biggest challenges in economics today is to explain what causes European unemployment. Commentators on the European situation often blame poorly designed

labor market institutions, a view that sometimes goes by the ugly name of “Eurosclerosis”. Economists advising governments on these issues share more or less the same diagnostic: Regulations such as hiring and firing restrictions faced by firms, as well as the generous welfare state that protects the unemployed, are behind the differential labor market performances of Europe and America. A number of countries have taken this view seriously. Great Britain and France are just two examples of countries that followed the economists’ advice and reduced hiring and firing restrictions in the mid-1980s to combat high unemployment. This view of the labor market has also inspired large reform programs in the less developed world, where unemployment has recently increased. In fact, deregulation of the labor market is part of what the IMF and the World Bank often call “second-generation reforms”.<sup>1</sup>

Since unemployment brings real misery to people’s lives, and job security provisions often involve delicate redistribution issues between richer firm owners and poorer workers, one would think that economists giving such advice know what they are doing. More precisely, one would think that there are hundreds of papers studying whether more flexibility does in fact reduce a country’s unemployment rate in practice. Sadly, this is not the case. To our knowledge, there is one panel study on the effects of labor market flexibility across countries (Lazear, 1990). And only a couple of cross-section studies, like the early one of Bertola (1990) based on evidence for 10 countries or that in the OECD Jobs Study (1994) based on 21 observations.<sup>2</sup> Addison and Grosso (1996) revise Lazear’s data and obtain different estimates with respect to unemployment (they find no evidence favoring the hypothesis that severance pay increase unemployment).<sup>3</sup> Gregg and Manning (1997) review some of the available evidence on the effects of labor market flexibility and argue that it is “*much less persuasive than is commonly believed*”, and that the profession’s “*faith in the merits of labor market de-regulation is misplaced*” (p. 395). There is, perhaps, no experience more sobering to an economist than to review the state-of-the-art evidence on the effects of firing costs and to reflect on the social costs of unemployment.

The contribution of this paper is empirical. We introduce a new data set on hiring and firing restrictions for 21 OECD countries for the 7-year period covering 1984–1990. The data are based on surveys of business people in the countries covered, so the indices we use are subjective in nature. We also use the new summary measure of the parameters of the unemployment insurance system compiled by the OECD in 1994, which constitutes a significant improvement on previous benefit data available in the profession. We then present an empirical analysis of the effect of flexibility on a number of labor market variables that follows and extends the contributions of Lazear (1990). Controlling for country and time fixed effects, and using dynamic panel data techniques developed by Arellano and Bond (1991), we find evidence that relaxing job security provisions increases the employment rate and the participation rate. The estimated

<sup>1</sup> The IMF suggested that Argentina should increase the flexibility of the labor market, after unemployment reached 18.6% following the pro-market reforms of the early 1990s.

<sup>2</sup> Even in-depth single country studies are relatively rare. The interested reader is referred to the work of Abraham and Houseman (1994), Kugler (1999) and Hunt (1994) and Autor (2003).

<sup>3</sup> They emphasize a number of differences with Lazear’s study (e.g. with respect to advance notice requirements), but they do find similar results with respect to three out of four variables.

effects seem large. The fixed effects estimate tells us that, if France were to reform its labor markets and make them as flexible as the American, its employment rate would increase by 1.6 percentage points.<sup>4</sup> This is equivalent to 14% of the employment rate gap between the two countries. In order to express this effect in terms of *GDP* per capita, we note that it implies an increase in total employment of 2.8%. In the short run, the estimated effects are stronger for females than for males, although interestingly both groups have roughly similar long run coefficients. There is also evidence that a more flexible labor market leads to lower unemployment rates and to a lower proportion of long-term unemployed in the unemployment pool. The effect of unemployment benefits on these variables is less clear-cut. As a general point, we think it is reassuring that, in spite of using such a different approach, our results are not out of line with those obtained by Lazear. We also document the basic correlation of flexibility with inflows and the rate of unfilled vacancies, and review the hypotheses that inflexible labor markets produce “jobless recoveries” and introduce more unemployment persistence.

The main empirical evidence on the effect of labor market flexibility that we have available today is presented in Lazear (1990). He uses data on severance pay and periods of notice required before employment termination for 22 developed countries for the period 1956–1984, and finds some evidence that they have a negative relationship with the employment rate and a positive one with the unemployment rate. For example, Lazear finds that the amount of money paid to the worker as severance enters negatively and significantly in univariate regressions on country means (18 observations) explaining the employment rate, the participation rate and the number of hours worked per week. The coefficient on severance pay in the unemployment regression is positive but insignificant, however. In univariate regressions explaining the unemployment rate and the number of hours worked that include country dummies (468 observations), the coefficient on severance pay keeps its sign and turns significant. It is insignificant, however, when explaining the employment rate or the rate of labor force participation (where it also changes sign).

Lazear points out a number of limitations in these data. Amongst them is the fact that information on one type of worker (blue collar with 10 years of service) is used as a proxy for the entire system. Second and more significantly, information on two types of institutions (amount of severance pay and months of advance notice before dismissal) are used to proxy for a large number of employment regulations that affect the flexibility of the labor market.<sup>5</sup> Clearly, flexibility of the labor market could be affected without showing up in these two series. Third, it does not allow for the fact

---

<sup>4</sup> France is the median country in terms of flexibility, though it is below the mean. See Table 1 for the full data description.

<sup>5</sup> For example, Grubb and Wells (1993) describe five other types of regulations that are relevant besides the restrictions on an employer’s freedom to dismiss workers. These include limits on the use (or the legal validity) of fixed-term contracts; limits on the use of temporary work agencies, restrictions on weekly hours of regular or overtime work; limits on shift, weekend and night work; and limits on employer’s use of part time work. The OCED Jobs Study (1994) notes that an employer’s freedom to dismiss workers can be restricted by a number of requirements other than a requirement of advance notice. These include a requirement of authorization by third parties (e.g. government, or trade union), provisions for appeal against unfair dismissal and the enforcement of these rules.

that countries differ in the degree of enforcement of these laws, and that other, perhaps informal, aspects may be more important than the written laws. Lastly, Lazear points out that “*for the most part, rules change once or twice during the period per country, so much of the mileage is cross-sectional rather than time-series*” (Lazear, 1990, p. 708). Yet, it is the best data that economists have available to study a most important set of issues.

The flexibility data used in this paper come from the *World Competitiveness Report* (WCR).<sup>6</sup> The WCR requests the opinion of a number of top and middle managers (on average 1,531 each year) on the flexibility enterprises have to adjust things like compensation and employment levels to economic realities in each of the countries covered. By its nature, these data avoid some of the objections raised to the data used by Lazear. For example, it uses information provided by business people who, presumably, are in a position to judge what aspects of flexibility laws actually affect business conditions. Furthermore, it passes simple validation tests. For example, it correlates well with the index of “*strictness of employment protection legislation*” constructed for the *OECD Jobs Study* (1994), arguably the most complete measure available, for the 1 year where both types of data are available (1989). There are, of course, limitations to the data we use. The time series dimension of the panel is considerably shorter than that of Lazear’s (7 versus 29 years). Importantly, the question asked is more vague than what ideally an economist would like to use. Furthermore, a lower set of answers in one country may simply reflect the fact that people there use a different cardinal ranking than people in other countries. Though some of these objections can be tackled in the empirical section, the fact remains that subjective responses should be treated with caution. However, we believe the topic to be of such economic and social significance, and the data that so far has been available to the profession to be of such poor quality, that a willingness to experiment with survey data is justified.<sup>7</sup>

In Section 2, we discuss briefly some of the theoretical background for our study, present our empirical strategy and explain the data used in the paper. Section 3 presents the empirical results while Section 4 concludes.

## 2. Theory, empirical strategy and data description

### 2.1. Theory

On the theoretical side, Lazear (1990) points out that if markets are complete, mandated severance payments should not have real effects. The argument is that the firm-worker pair can undo the firing costs imposed on them by a reverse transfer from the worker to the firm at the onset of the employment contract. Bertola (1990) finds that job security legislation does not bias labor demand toward lower average

<sup>6</sup> This is a publication of the IMD/World Economic Forum.

<sup>7</sup> Put another way, the data that we use have different problems to the data previously used in the literature. Thus, we view this paper as complementing Lazear’s approach with “hard” data.

employment at given wages in a simple dynamic economy. The intuition is that a firm subject to a positive shock will hire less workers than otherwise, but that firms subject to a negative shock will be less prone to firing. Thus, employment fluctuations are dampened, but average employment may be unchanged. The evidence he presents is based on Emerson (1988) and is consistent with this view. Bentolila and Bertola (1990) present a model where firing costs actually increase long-run employment.

On the other hand, Hopenhayn and Rogerson (1993) study a general equilibrium model with entry and exit of firms and calibrate it using data on firm level dynamics. They show that a tax on job destruction equal to 1 year's wage reduces the employment rate by roughly 2.5%. There are very large welfare costs in their model: The cost of the same tax in terms of consumption is over 2%. The effects of firing costs on investment are also studied by Risager and Sorensen (1997) using Bertola's model. A recent paper by Alvarez and Veracierto (1998) extends Hopenhayn and Rogerson (1993) by introducing frictions in a world without perfect insurance markets. They find that severance payments can increase welfare. The reduction in firm layoffs and the increase in the agents' search efforts (because employment is more desirable) reduce unemployment enough to compensate for lower consumption levels (productivity also falls). Other contributions in the search literature have emphasized different effects of firing restrictions (for a general treatment, see Pissarides (1990); see Mortensen and Pissarides (1999a, b) for a review). Boeri (1998), for example, presents a model where job security provisions, job-to-job shifts and long-term unemployment can coexist. Another paper by Garibaldi (1998) studies how firing restrictions reduce the volatility of job destruction and the amount of job reallocation, with unemployment remaining approximately constant. Interestingly, the effect of firing restrictions on labor force participation is theoretically ambiguous. Such restrictions could lead to higher participation rates if unproductive workers, who would otherwise exit the labor force, are locked into jobs. But they could lead to lower participation if labor supply decisions are made at the household level and a match that is more secure for one member leads other members to stop or postpone their job search activities (see, for example, Pissarides (2001) for a model that gives an insurance role to employment protection in the absence of perfect insurance markets). Saint Paul (1996a) developed a matching model to study the interaction of technological advances with firing costs in the determination of unemployment, while Saint Paul (1997) studies the effect of higher firing restrictions on a country's competitiveness and pattern of trade. Saint Paul also pioneered the study of the determinants of firing restrictions, a topic to which we will return in Section 3.2 (see Saint Paul (1996b) for a review, and Saint Paul (2002) for a compelling model; see also Wright (1986), Di Tella and MacCulloch (2000, 2002) and Hassler et al. (1999) for work on unemployment insurance).

A recent paper by Bertola and Rogerson (1997) shows that we can have similar rates of job creation and destruction across countries despite there being very different degrees of labor market flexibility, if other institutions lead to wage compression. Thus, lower flows due to job security provisions, the argument goes, could be compensated by higher employer-initiated job turnover originating in the generosity of the European welfare state. Thus, the paper points to the importance of controlling for the generosity of the welfare state when investigating the effects of flexibility on the workings of the

labor markets. All regressions in our paper include the new summary measure of the parameters of the unemployment benefit system compiled by the *OECD Jobs Study* (1994).<sup>8</sup>

## 2.2. Empirical strategy

In order to study the effect of hiring and firing restrictions on the performance of the labor market, we estimate regressions of the form

$$VAR_{it} = \alpha_1 + \alpha_2 Flexibility_{it} + \alpha_3 Benefit_{it} + \mu_i + v_t + \varepsilon_{it}, \quad (1)$$

where  $VAR$  represents the variables of interest. For purposes of comparison with Lazear's results, in the main tables these are the employment rate, the rate of participation in the labor force, the average number of hours worked in manufacturing and the unemployment rate. We also study the effect of flexibility on the proportion of long-term unemployed in the unemployment pool, the vacancy rate and the inflow rate. Variables are defined in Appendix A.

The estimation strategy we use follows Lazear's approach of using a parsimonious reduced form specification. We also show the results of different specifications, rather than committing to one early on. The main differences with Lazear's estimation strategy are that: (1) We do not impose the restriction of a quadratic time trend but report regressions controlling for year fixed effects (i.e. we include year dummies instead of the time trend and the time trend squared used by Lazear); (2) we control in all our regressions for the generosity of the welfare state (as proxied by unemployment benefits); and (3) we report regressions where lagged variables are included since firing costs are sometimes expected to affect the flows (but not directly the stocks) in the labor market.

## 2.3. Construction of the data set

The indicator of labor market flexibility used in this paper comes from the WCR, a publication of the EMF foundation in Geneva. It covers 21 countries (a list is given in Appendix A) and covers the period 1984–1990. Thus, the first year for which we have data is also the last year covered by the Lazear study. The WCR was used before by economists studying investment and growth (De Long and Summers, 1991) and studying corruption and competition (Ades and Di Tella, 1999), but its use as a source of labor market flexibility data is new. It consists of yearly surveys conducted amongst

---

<sup>8</sup> It is calculated as the pre-tax average of the replacement ratios for two earnings level, three family situations and three durations of unemployment. Although not perfect, the data begin to address some of the criticisms raised by Atkinson and Micklewright (1991) to the data previously used in the literature. A number of studies have found evidence that unemployment benefit generosity increases unemployment at the micro level (e.g. Katz and Meyer, 1990). Cross-country panel studies, on the other hand, have failed to uncover significant effects of unemployment benefits on the unemployment rate, once country and year fixed effects have been included. One of the potential reasons is that the benefit data used are very poor. For example, Layard et al. (1991) uses the 1985 duration of unemployment benefits as an indicator of generosity for the whole sample.

chief executive officers and economic leaders in the countries covered, who are mailed a questionnaire containing a large number of questions on their country's competitiveness (unfortunately sometimes it can contain as many as 90 questions). The surveys were sent out to "*Company CEO's, economic and financial experts, bankers, heads of foreign owned subsidiaries of multinational companies, as well as key personalities of the economic press, trade unions and business associations*".

The survey question that is used (classified as 2.17 *LABOR-COST FLEXIBILITY* in 1984) asked the respondents: "*Flexibility of enterprises to adjust job security and compensation standards to economic realities: 0 = none at all, to 100 = a great deal*". This question was changed in 1990 to "*Flexibility of management to adjust employment levels during difficult periods: 0 = low, to 100 = high*". It was dropped altogether in subsequent years. The survey criteria presented in the WCR constitute the average value of respondent's ratings for their respective countries. Respondents were invited to rate the performance of the country in which they resided on 91 criteria, on a scale of 1 to 6. They were "*thus presented with a choice of six values which prevented them from giving a middle value. A 1 to 3 ranking implied a negative assessment, and a 4 to 6 rating a positive one.*" The results presented in the WCR are transformations from the 1–6 to a 0–100 scale. In 1984, there were 5,500 questionnaires sent out and 1,100 were returned. In 1985, there were 7,513 questionnaires sent out and 1,598 returned. In 1986, there were 1,369 returned questionnaires and in 1988 there were 1,937 returned. In 1989, there were 12,000 questionnaires sent out to a similar sample of people of which 1,800 were returned. Finally, in 1990, there were 10,000 survey questionnaires sent out of which 1,384 were returned. The firms are not randomly selected. This has the obvious drawback of not being a truly random selection of firms but the advantage that the firms may share a common benchmark (such as the US).<sup>9</sup> There was no WCR containing 1987 data so the 1986 and 1988 observations were interpolated linearly to obtain observations for 1987.

It is clear that there is a trade-off in using survey data. The data seem to be less precisely defined than what we would ideally like. There is no survey question that is easier to interpret data on than, say, the number of months' written notice required before termination to workers with 10 years of service. On the other hand, our survey measure is more likely to capture the many dimensions that such institutional arrangements associated with employment protection laws encompass. For example, much of the impact of hiring and firing costs comes from the degree of enforcement of the different aspects of the law, such as whether or not there is rightful dismissal, or the appropriate wage/length of employment over which to calculate severance pay. It is also well known that in some countries, like France, advance notice before dismissal given orally is more important than that advance notice administered in written form.<sup>10</sup> It is easier to capture this information through survey questions registering opinions than with easy to quantify data describing the actual laws, unless it is done in

<sup>9</sup> Response rates were similar in later years. For example, in 1991 there were 12,000 questionnaires sent out of which 1,484 were returned. In 1993 WCR, there were 2,160 returns out of 10,300 questionnaires sent out, although this issue did not contain the flexibility question.

<sup>10</sup> Some people call this "fuzzy advance notice".

a very meticulous manner. Another important advantage is that the respondents have actual experience and knowledge of the workings of the labor market in question, so presumably they know the relevance, if any, of changes in the written laws. In any case, measurement error in the data would bias the regression coefficients to zero. Also note that the size of the surveys implies that the variance of the observations would be considerably lower than would be the case with, for example, individual level data.<sup>11</sup>

Another potential source of concern is the fact that the question changes in 1990, omitting any reference to changes in wages. Employers in industrial democracies rarely cut nominal wages, even in countries where it could be done in principle, like the US, so this does not strike us as particularly problematic. As a check, however, we re-estimated our regressions without 1990 and the main results do not change. For example, if we re-estimate the effect of flexibility on our main variables of interest using the LSDV specification with country and time fixed effects without the 1990 observations, we find that the results improve (in terms of size and significance) in every case. Excluding the interpolated year (1987) also improves the main results in the paper.

### 2.3.1. Cross-section validation

As with all subjective data, it is important to see if some of the survey information being used can be related to hard data. The WCR survey measure of labor market flexibility can be compared with other measures that are available for a limited cross section of countries. For example, the [OECD Jobs Study \(1994\)](#) has produced a cross-country index of the “strictness” of labor employment protection legislation for 1989. The OECD index is based on an overall assessment of the extent of regular procedural inconveniences faced by employers such as delays to the start of notice of dismissal, the amount of notice and severance pay for no-fault dismissals, and also the difficulty of dismissal. The difficulty of dismissal includes assessments of the definition of unfair dismissal, trial periods and reinstatements.<sup>12</sup> The correlation coefficient of the WCR survey measure of labor market flexibility in 1989 (where high values denote high flexibility) with the 1989 OECD indicator (where high values denote greater strictness) is  $-0.75$ . Higher levels of flexibility measured by the WCR survey responses are strongly associated with lower levels of employment protection strictness measured by

---

<sup>11</sup> There were more countries covered in the questionnaire than the ones used in this study (because data on other variables of interest is lacking). For example, the 1985 data comes from 1,598 answers from 31 countries, so the average is 52. This may underestimate the average number of respondents for the countries we study in this paper as they are all OECD countries, and it is likely that more questionnaires were sent and returned to these countries than to other countries in the survey (like Mexico, Brazil, Malaysia, Thailand, Korea, etc).

<sup>12</sup> The Jobs Study (1994) notes researchers have constructed various summary indicators to describe the strictness of employment protection in each nation but that “*given the complexity of the phenomenon, summary indicators are inevitably somewhat arbitrary*” (p. 70). Norway and Sweden have relatively high rankings on the OECD scale of strictness of employment protection. This is due to, for example, legislative provisions allowing courts to order reinstatement of unfairly dismissed employees in Norway and the 6-month trial period in Sweden that must be given to dismiss a 35-year-old worker.

the OECD quantification of legal data, as we can reject the hypothesis of independence of the two variables.

A second measure of the strictness of employment protection has been produced by the International Organisation of Employers (IOE) (1988). They assessed the importance of obstacles to termination or use of regular and fixed-term contracts on a 0–3 scale across countries in 1985. Regulatory constraints were classified as insignificant (0), minor, serious or fundamental (3). The correlation coefficient of the WCR survey measure of labor market flexibility in 1985 with the 1985 IOE indicator is  $-0.59$ . Higher levels of flexibility measured by the WCR survey responses are associated with lower levels of employment protection strictness measured by the IOE, although the correlation is not as strong as before (independence can again be comfortably rejected). Lastly, we also correlate the WCR data to the index used by Bertola (1990) based on information presented in Emerson (1988), and extended in the OECD Jobs Study (1994) to cover 21 countries. The correlation coefficient is  $-0.58$  and we can reject the null of zero correlation.<sup>13</sup>

### 2.3.2. Time series validation

Recently, Saint Paul (1996a, b) has coded a number of selected events of changes in job protection legislation that have occurred in Europe over the last 25 years. He classifies each event according to whether job protection legislation has become more or less restrictive. There are 12 events that have occurred in dates and countries for which we also have WCR data. For nine of the 12 events, Saint Paul records an event with the same sign as our data would predict (we create a new variable  $\Delta Flexibility_t = Flexibility_t - Flexibility_{t-1}$ ). Thus, for three events our data disagree with Saint Paul's classification. These are: The UK in 1990 (when there was an increase in the employment duration required to benefit from unfair dismissal protection), Italy in 1987 (when there was a liberalization of determined duration contracts) and Italy in 1990 when there was an extension of unfair dismissal legislation to smaller firms. In the last two events in Italy, however, the variable  $\Delta Flexibility$  only registers very small values (5.9% and 5.8% of a standard deviation in  $\Delta Flexibility$ ).

A further concern with the WCR flexibility indicator is that, being assessments of business persons, they may be affected by how well firms are doing. Maybe when a country is in a recession managers will become aware that it is tough to adjust employment levels whereas in a booming economy managers do not recall these difficulties. Or maybe managers are just more positive all round in economic booms. We test the hypothesis that the WCR flexibility variable is correlated with a number of indicators of the business cycle and do not find evidence of such a strong correlation in any of them. For example, in Table 2 in Appendix B we study the correlation between flexibility and measures of (i) aggregate *GDP* (at constant 1985 prices), (ii) the change in *GDP* ( $\Delta GDP$ ), (iii) changes in industrial production (proxied by value-added in

<sup>13</sup> As a further check, we studied the correlation of our flexibility data with a measure of flexibility obtained by Blanchflower (1999) using micro-survey data on individual willingness to move area of residence for 1995. Again we could reject independence between this measure and our *Flexibility* index (for 1990).

industry), (iv) changes in the size of the service sector (proxied by value-added in services) and (v) changes in openness. The disaggregation of  $\Delta GDP$  into industry and service sectors is done since hiring and firing restrictions may affect these two groups differently.  $\Delta Openness$  is included as a proxy for industrial turbulence, since more open economies may be more exposed to external shocks (see Cameron, 1978; Rodrik, 1998). Pearson's correlation coefficient is reported. For example, the correlation coefficient between *Flexibility* and  $\Delta Industrial\ production$  is 0.022. It is  $-0.006$  with  $\Delta Openness$ . All the above five correlations are insignificant (so is Spearman's rho) so we cannot reject the hypothesis that the *Flexibility* variable and each of these measures of the business cycle (and industrial turbulence) are independent. Controlling for country and year fixed effects,  $\Delta GDP$  has a positive but insignificant estimated effect on *Flexibility* (it is significant at the 85% level) and  $\Delta Industrial\ production$  has a positive but insignificant effect (at the 89% level).  $\Delta Service\ sector$  and  $\Delta Openness$  also have insignificant effects. Still, the empirical section will present regression estimates where flexibility appears lagged 1 year, so the possibility of joint determination of flexibility with economic variables is reduced. We will also present regressions that control for the state of the economy (including  $\Delta GDP$  and  $\Delta Industrial\ production$ ). In regressions with country and year effects, the relationship between real wages and flexibility is negative (not positive as could be expected if *Flexibility* were just a proxy for the business cycle).

We use the recently published OECD summary measure of the parameters of the unemployment insurance system (OECD Jobs Study, 1994) as a measure of the generosity of a country's welfare state. It is calculated as the pre-tax average of the replacement ratios for two earnings levels (average earnings and two-thirds average earnings), three family situations (single, with dependent spouse and with spouse in work) and three durations of unemployment (first year, second and third years, and fourth and fifth years).<sup>14</sup> It is not weighted by the composition of unemployment in any particular place or period. These data represent a significant improvement over previous measures used. Consider the case of an unmarried worker in Norway. The worker's unemployment benefit replacement rate would be 62% in the first year, 41% in the second and third years and 14% in the fourth and fifth years. These numbers do not vary according to family circumstance. The comparable numbers for the USA would be 24%, 5% and 5%, respectively, but would increase to 26% in the first year if the worker had a dependent spouse and fall to 21% if the worker had a spouse that worked. In the second, third, fourth and fifth years unemployment benefits would be zero if the worker had a spouse that worked and 10% if the spouse was dependent. Atkinson and Micklewright (1991) have emphasized that this is a desirable feature of benefit data since cuts in one type of benefit are often offset by a corresponding increase in another type. Due to the complexity of the OECD calculations of benefit generosity, measurements were made at 2-year intervals. Consequently, observations were interpolated to obtain data for consecutive years.

<sup>14</sup> The pre-tax replacement rate is defined as benefit entitlement over previous earnings, all pre-tax.

We completed our data set with the employment rate (defined as total civilian employment divided by the population aged between 15 and 64 years old), the participation rate (defined as total civilian employment plus total unemployment divided by the population aged between 15 and 64 years) and the average number of weekly hours worked in the manufacturing sector. We also collected the unemployment rate, the rate of unfilled vacancies and the rate of long-term unemployment (defined as the number of workers who have been out of work for 6 months or more as a percentage of total unemployment). The source of these data is the Centre for Economic Performance OECD 1950–1990 updated data set compiled by Bagliano et al. (1992). Pascal Marianna at the OECD kindly provided us with the latest updated file of inflow data (the number of unemployed persons with duration less than 1 month divided by total employment).

Data definitions and summary features of the data appear in Appendix A. The raw data show that countries with more flexible labor markets have higher employment rates, lower unemployment rates and lower proportions of long-term unemployed, though the relationships are by no means monotonic.

### 3. Empirical results

#### 3.1. Basic evidence on labor market flexibility

We begin our empirical analysis by studying the effect of labor market flexibility on the employment rate. Regression (1) in Table 3A estimates the effect of *Flexibility* and *Benefits* on the employment rate using generalized least-squares random effects (Balestra–Nerlove). For purposes of comparison, Table VI on p. 716 in Lazear (1990) presents hypothesis tests where the lack of independence over time of the error term in a given country has been taken into account. Regression (1) in Table 3A shows that countries with more flexible labor markets also have higher employment rates. The effect of unemployment benefits is negative but insignificant. The estimated flexibility effect is large. If the estimated effects are taken to be causal, a 1 standard deviation increase in the flexibility of the labor market will bring about an increase in the employment rate of 1.9 percentage points, almost 20% of a standard deviation in the *Employment* variable. In other words, if France were to reform its labor market to make it as flexible as that in the United States during this period, then the employment rate would increase by 4.4 percentage points. That is, different degrees of flexibility in the labor market would account for almost 38% of the different employment rates of the US and France in the late 1980s. The estimated effect means that, going from the bottom to the top of the sample (from Spain to the US) in terms of flexibility would increase Spanish employment by almost 6.2 percentage points. In order to estimate its effect on French *GDP* per capita we note that making French labor markets as flexible as those in America would mean that total employment would increase by a large 7.6%. The magnitude of the estimated effects is perhaps surprising (and we will come back to this issue) but we note that the basic evidence is inconsistent with the predictions of Bertola (1990) and Bentolila and Bertola (1990) and are broadly consistent with the Hopenhayn and Rogerson (1993) model.

Another way to correct for the lack of independence over time of the error term in each country is to control for country fixed effects. This method has the considerable advantage of controlling for the incidence of time-invariant omitted variables that may be correlated with the other explanatory variables.<sup>15</sup> The estimators in regression (2) of Table 3A are least squares with dummy variables (LSDV). The effect of flexibility on the employment rate has a similar sign and size to that in regression (1) and is significant at the 5% level, while the coefficient on unemployment benefits is insignificant. This stands in contrast to Lazear (1990, Table V, p. 714) where the effects of severance pay on the employment rate are insignificant once he controls for country dummies. Regression (3) includes year dummies. Controlling for year fixed effects adds the requirement that a country with a higher than average flexibility reading 1 year must also experience a higher than average (for the countries) employment rate (in order for a significant coefficient to be obtained). The effect of *Flexibility* is positive and significant, though of smaller size than the previous estimates. If France were to increase the flexibility of its labor markets to American levels, its employment rate would increase by 1.6 percentage points, now only 14% of the difference in the employment rates of the two countries.<sup>16</sup> In order to express this employment gain in terms of increases in French *GDP* per capita we note that this increases French total employment by 2.8%. There are some negative effects of unemployment benefits (significant at the 9% level only).

As noted in Section 2.3, a potential objection to these results is that there is possible contamination of the data arising from the stage of the business cycle. When the economy is in recession firms are more likely to be firing than hiring and so employment protection legislation may impose binding constraints on firms. If managers' responses to our survey question are subsequently in the direction of greater inflexibility at such times, even though the parameters of the system have not changed, then the interpretation of the results would be different. Alternatively, when the economy is growing the existing employment laws may be of less consequence to firms so managers' responses may indicate a higher degree of labor market flexibility in these times. We attempt to deal with this concern by reporting regressions that control for the change in total *GDP*,  $\Delta GDP$ , in every one of our tables. The results remain almost identical (that is, the coefficient on *Flexibility* retains its size and sign at the same level of significance). For example, in regression (3), once we control for  $\Delta GDP$  the coefficient on flexibility changes from 0.053 to 0.052 and the standard error remains equal to 0.026 (reported in note b in Table 3A; see also Table 7 for further tests).

<sup>15</sup> Another reason is that we use Hausman's (1978) specification test to examine if random effects are appropriate. The test statistic for regression (1), which has a chi-squared distribution with two degrees of freedom, has a value of 4.76. The probability of obtaining a value at least as large as 4.76 is consequently 0.0923. Hence, there is some evidence that the assumption of the random effects being uncorrelated with the explanatory variables is incorrect (or that the model is misspecified). Thus, we also report regressions obtained by estimation with LSDV.

<sup>16</sup> We can get another sense of the size of this effect by going from the top to the bottom of the sample. Making the Spanish labor market as flexible as the American means adding another 2.3 percentage points to the Spanish employment rate.

Theoretical models of employment alert us to the possibility that hiring and firing restrictions affect stock variables (like the employment rate) only through its effects on the flows in and out of employment. It is possible, then, that *Flexibility* affects *Employment* with a lag, and that the lag exceeds 1 year. Regression (4) in Table 3A indicates that the 1-year lag of *Flexibility* enters positively and significantly in an employment regression controlling for country and year fixed effects, and is almost 64% larger than the contemporaneous effect estimated in regression (3). If France were to have US flexibility levels, its employment rate would increase 2.6 percentage points a year later, or 22% of the actual difference in employment rates. Using a 2-year lag also yields positive and significant estimate of the effect of flexibility on the employment rate, though the number of observations drops to 102. A virtue of these estimates is that if the flexibility data were still suspect of being contaminated by the economic atmosphere as perceived by the respondents, then this would be less likely to show up when 1- or 2-year lags are used.<sup>17</sup>

An even more stringent test for the hypothesis that flexibility affects labor market performance is to include a lagged dependent variable. Again, from a theoretical perspective, it could be argued that the long-run response of the labor market to flexibility differs in the short- and long runs, or that there exist “adjustment costs” that justify this specification. Another reason we could want to include a lagged dependent variable is that it may help proxy for slower moving omitted variables that are not captured by the controls included. At any rate, it seems natural to keep an open mind at this stage of our empirical (and theoretical) knowledge on the subject. Regression (5) in Table 3A estimates the effect of flexibility on employment controlling for unemployment benefits and lagged employment. The presence of a lagged dependent variable on the right-hand side of (5) introduces a bias when estimation is by LSDV. Perhaps the easiest way to see this is to note that first differencing the data makes the lagged dependent variable correlated with the error term. Since the bias may be particularly large when the time series dimension of the panel is short, we correct for this using the generalized method of moments (GMM) technique (see Arellano and Bond, 1991). Valid instruments are specified in each time period for the first-differenced equations. Regression (5) in Table 3A controls for year fixed effects by including year dummy variables, controls for country fixed effects by first differencing the data, and then controls for the dynamic panel data bias by instrumenting the differenced lagged dependent variable ( $\Delta y_{it-1}$ ) with lagged levels of dependent variables dated  $t - 2$  and earlier. The coefficient on *Flexibility* is still positive and significant. The size is not too different from that in regression (3).

The long-run effects are quite large now. If France were to increase the flexibility of its labor markets to the level of the US, the employment rate would increase by 1.5 percentage points. In the long run, the effect would be to increase the employment rate a full 3.6 percentage points, or 31% of the France–US employment rate gap. The effect of unemployment benefits is insignificant. Lastly, regression (6) in Table 3A includes the more general specification with lags of the dependent and independent variables. The current level of *Flexibility* is still positive and comfortably significant.

---

<sup>17</sup> As we mentioned in Section 2.2, we did not find evidence of such a correlation.

The first lag of flexibility is positive but insignificant, and unemployment benefits and its lag enter significantly in the employment regression. We cannot reject equality of the unemployment benefits coefficients (in absolute value) so it seems that there is some evidence that positive changes in *Benefits* decrease the employment rate.

Theory leads us to expect different effects of job security provisions across groups, depending on their roles in the labor market.<sup>18</sup> In the next two tables, we study the effect of labor market flexibility on the employment rates of men and women. The general message of Tables 3B and C is that the estimated flexibility effects on female employment rate are larger than the corresponding effects in the labor market for males. The sign and significance of the coefficients in Table 3B are almost identical to those in Table 3A. The size of the coefficients is also very similar. This result would also seem to indicate that managers' responses to the survey question are unlikely to depend on the stage of the business cycle since under this scenario we would expect to find the similar effects for both men and women. Including  $\Delta GDP$  leaves the coefficients on *Flexibility* almost identical to their previous levels (see footnote b in Tables 3B and C). In terms of size, however, one of the most interesting differences is the estimated long-run effect of flexibility on employment of females compared to that of males. Comparison of the estimated effects in regression (5) in Tables 3B and C seem to indicate that the short-run effect of flexibility is larger for women than for men, but that in the long run they have approximately similar coefficients. If France were to increase the flexibility of its labor markets to levels comparable to those prevailing in the US, regression (5) in Table 3B predicts that there would be an increase in female employment equal to almost 1 percentage point in the short run, and a 1.6 percentage point increase in the long run. Regression (5) in Table 3C predicts that such a movement would increase the employment rate of men by over 0.36 of a percentage point in the short run, and almost 1.3 percentage points in the long run.

We also study the effect of flexibility on labor force participation. As pointed out in the theory section, the expected effect is ambiguous. In Table 4A, we again present a parsimonious, reduced form approach showing a number of different specifications. Regression (1) finds positive and significant effects of flexibility on participation rates. The effect is large: If France turns into the US in terms of flexibility, the participation rate would increase by 3.5 percentage points, over 36% of the actual difference in participation rates between the two countries. Again, in contrast to Lazear, the effect survives the inclusion of country and year dummies, the inclusion of lagged independent variables and the inclusion of a lagged dependent variable (estimated with GMM techniques). In some regressions there are negative effects of unemployment benefits.

The literature suggests some stylized facts about female labor force participation (e.g. it is lower than that for males and it is larger for single women than for married women; see Killingsworth and Heckman, (1986)). This leads us to expect that the insurance effect would be stronger for females. The idea, to put it simply, is that there

<sup>18</sup> For example, Lazear has a short section on the effects of severance pay on the labor market performance of the young.

will be higher female labor force participation when men face higher probabilities of losing their jobs (and higher accessions). Table 4B shows this is largely the case in our sample, with well-defined and positive effects of flexibility on female labor force participation. Table 4C shows that the effect of flexibility for men is weaker all round. When it is significantly different from zero, it is substantially smaller in size than female effects.

Table 5A presents unemployment regressions. Regression (1) finds that random effects estimation suggests that countries with more flexible labor markets have lower unemployment rates. The estimated effects are large. Again taking the relationship to be causal, if France were to reform its labor market to have the flexibility levels observed in the US, it would have an unemployment rate which was lower by more than 1.7 percentage points. That is, different flexibility levels would explain almost 47% of the different unemployment experiences of the two countries during the mid- to late 1980s. Regression (2) shows similar results when controlling for country fixed effects. Importantly, we do not find significant effects of flexibility on the unemployment rate in regression (3), where we control for both country and year fixed effects, although the coefficient is still negative. Using robust regression techniques to reduce the influence of outliers yields a larger, negative coefficient though still insignificant (significant at the 22% level, results available upon request). As we explained earlier, flexibility may affect labor market flows, and thus could affect the unemployment rate with a lag. Regression (4) finds that an increase in flexibility today would only decrease the unemployment rate next year. The effect of flexibility lagged is significant at conventional levels and its size is almost 10% smaller (in absolute terms) than that in regression (2). Regressions (5) and (6) in Table 5A include a lagged dependent variable and only find very weak negative effects of flexibility on unemployment.

A number of economists have predicted adverse effects of inflexible labor markets on the composition of unemployment (e.g. McCormick, 1991). Table 5B studies long-term unemployment. Regressions (1) and (2) show that countries with more flexible labor markets are associated with a lower proportion of long-term unemployed in the unemployment pool when estimation is by random effects and LSDV (country dummies only). Given the effects of flexibility in other regressions, the coefficients are rather small. If the relationship is taken as causal, regression (2) predicts that if France were to reform its labor market in order to match US flexibility levels, the proportion of long-term unemployed would fall 4.6 percentage points, almost 9% of the long-term unemployment gap between the two countries. When we also include year dummies in Eq. (3), the coefficient on flexibility becomes insignificant (though still negative). The lagged specification used in Eq. (4) finds some evidence of negative effects of flexibility, significant only at the 7% level. Re-estimation of regression (3) with robust regression techniques to control for the influence of outliers yields a much higher coefficient on flexibility in absolute value ( $-0.191$ , s.e.  $0.072$ ), significant at the 1% level. The same is true when regression (4) is re-estimated with robust regression techniques, where the negative coefficient on the lag of flexibility is now significant at the 1% level. Regressions (5) and (6) do not find strong contemporaneous effects. There is some evidence of lagged effects of flexibility on long-term unemployment in Eq. (6) though the number of observations drops as low as 89.

### 3.2. Causality and non-linearities

It has been pointed out, however, that unemployment may cause changes in labor market institutions (see Lazear (1990) and Saint Paul (1996a, b, 2002) on flexibility and Wright (1986), Atkinson (1990), Di Tella and MacCulloch (2000, 2002) and Hassler et al. (1999) on unemployment benefits). Thus, there may be a simultaneity bias in the flexibility coefficient in unemployment regressions. Lack of suitable instruments leads us to focus on timing to shed at least some light on these issues. If causation runs from say, unemployment to flexibility, we would expect previous experience with unemployment to predict movements in labor market flexibility. The fact that we are working with only seven time periods, however, reduces the usefulness of examining Granger-causality for individual countries. Thus, we first run a panel regression of  $\Delta Flexibility_t$  on unemployment lagged, employment lagged and participation rate lagged (this is the specification used in Lazear (1990); see Table IX). None of the coefficients are significant. The same is true if we restrict attention to unemployment. This is shown in regressions (1) and (2) in Table 6A. Comparing regressions (2) and (3), we can see that flexibility lagged is a somewhat better predictor of the change in unemployment than unemployment lagged is a predictor for the change in flexibility, though the effect is not strong. It is also interesting to run separate unemployment and flexibility regressions on unemployment and flexibility lagged once, and unemployment and flexibility lagged twice. The effects are again more supportive of the idea that flexibility causes unemployment than the other way around. Thus, the evidence reported in Table 6A, based on the extremely limited data available for this type of exercise, is not supportive of the reverse causality hypothesis.

We also made an attempt to instrument for *Flexibility* in both the employment and participation rate regressions. The instrument chosen was *Right Wing* politics. This variable that we constructed is meant to capture the degree to which political preferences in the country lean towards the right. It is similar to those employed by political scientists to indicate the left/right position of a government and is constructed in two steps. In the first step, we collect the number of votes received by each party participating in cabinet and express them as a percentage of the total votes received by all parties with cabinet representation. This percentage of support is then multiplied in the second step by a left/right political scale (from Castles and Mair, 1984) and summed across all the cabinet parties to give a continuous variable. A shift to more *Right Wing* government leads to significantly more *Flexibility*. Using this instrument in a two-stage least-squares regression, the coefficient on *Flexibility* in the employment rate equation becomes equal to 0.23, significant at the 10% level (using the same specification as in column (3) of Table 3A). In the participation rate equation, the coefficient on *Flexibility* becomes equal to 0.26, significant at the 5% level (using the same specification as in column (3) of Table 5A).

Lazear suggests that the effect of flexibility in the labor market may be non-linear. He suggests that, once employment restrictions are severe enough, firms may stop firing workers. Unlike Lazear, we find some evidence favoring a specification that includes a quadratic *Flexibility* term, particularly in the female sub-sample with respect

to employment and participation rates. The female employment regression is included in Table 6A as an illustration (see Eq. (6)).

### 3.3. Adding more controls

Another source of potential concern is that the level of unemployment benefits is the only control included in our regressions. Although Lazear (1990) runs, essentially, univariate regressions, there is a large literature that studies the role of labor market institutions in shaping unemployment (see, for example, Phelps, 1994). Table 6B presents regressions where some of the variables identified in this literature are included as controls. Information is available for only 1 year on some of these variables (e.g. home ownership) when we also have the flexibility data. Thus, we concentrate on regressions that control for random effects.

Regression (1) in Table 6B presents an employment regression similar to the first regression in Table 3A with three extra controls: union coverage, decentralization and home ownership. *Union Coverage* is defined as the percentage of workers covered by collective agreements. In some countries, like France or Spain, this number can be significantly larger than union density (source is Appendix 1.4 in Layard et al., 1991). *Decentralization* refers to the level at which wage bargains occur (the source is a ranking constructed by Calmfors and Driffill (1988)). *Home Ownership* is the percent of households that are owner occupied in 1990 (census data, see Oswald, 1996). The basic result is that the coefficient on *Flexibility* is still positive, comfortably significant and of almost identical size as that in regression (1) in Table 3A. The other variables also enter the regression with the expected sign and are often significant (the exceptions are unemployment benefits and home ownership). In terms of comparative size the effect is only moderate. In an average year, it explains about 26% of the employment difference between Spain and the US, which is less than what the gap in the *Union* and *Decentralization* variables between the two countries can explain. The rest of Table 6B shows that including these three controls does not change the results we obtained earlier with respect to participation rates, unemployment rates and proportion of long-term unemployment in the unemployment pool. The same is true when we study females separately from males (results available on request).

Table 6C provides more robustness tests, but now adding measures of labor taxation. The former variable was the focus of the study by Daveri and Tabellini (2000) about how taxes affected employment outcomes. Our regressions include a full set of country and year fixed effects which means that we are now unable to identify effects of variables for which we do not have time series information (such as home ownership). Comparable results using our base specifications are found in column (3) in Tables 3A, 4A and 5A. For example, in the employment rate regression the coefficient on *Flexibility* changes from 0.053 in Eq. (3) in Table 3A to 0.050 in Eq. (1) in Table 6C, once the fuller set of controls has been added. In the participation rate regression, the coefficient on *Flexibility* changes from 0.059 in Eq. (3) in Table 4A to 0.044 in Eq. (2) in Table 6C with the fuller set of controls. The significance level of *Flexibility* is 6% in the employment regression and 5% in the participation regression. There also exists a negative and significant effect of *Employment taxes* on both employment

and participation (at the 5% level). A one standard deviation increase in employment taxes (equivalent to adding 10.6 percentage points onto employers' contributions as a proportion of total employee compensation) is expected to decrease the employment rate by 0.6 of 1 standard deviation (or 6.1 percentage points) and the participation rate by 0.7 of 1 standard deviation (or 6.4 percentage points). These results all remain robust to controlling for the state of the economy, such as by the inclusion of a term for  $\Delta GDP$  (reported in the footnotes) as well as terms for  $\Delta Industrial\ production$  and  $\Delta Service\ sector$ .<sup>19</sup>

Regressions (4)–(6) add interaction terms between *Flexibility* and *Employment taxes* as well as between *Benefits* and *Employment taxes*. There is no evidence of strong interaction effects in the case of *Flexibility*, but some evidence that the effect of *Employment taxes* is more negative in the presence of high unemployment benefits. We also experimented with controls for openness, terms of trade (i.e. ratio of average value of exports to average value of imports) and measures of the government's budget surplus/deficit. With these three extra controls added (as well as the four control variables included above plus the two interaction terms), the coefficient on *Flexibility* equalled 0.111 in the employment rate regression and 0.097 in the participation regression, both significant at the 5% level.

Table 7 reports results when the state of the economy, proxied by both  $\Delta GDP$  and  $\Delta Industrial\ production$ , are included together with interaction effects, as suggested by a referee. If managers tend to stress severance costs when the economy is in a downturn, then the effect of regulation could be overestimated. One way to test for this is to interact the size or sign of  $\Delta GDP$  and  $\Delta Industrial\ production$  with the *Flexibility* index. Regressions (1) and (2) include both  $\Delta GDP$  and its interaction with *Flexibility* in employment and participation rate regressions, respectively. The results remain similar to before. For example, *Flexibility* has a positive effect on the employment rate equal to 0.051, significant at the 5% level, in regression (1). The interaction term is positive but insignificant. Since hiring/firing costs may affect the industrial sector in particular, regressions (3) and (4) include  $\Delta Industrial\ production$ , interacted with *Flexibility*. The basic results again remain similar. When the sign (i.e. positive or negative) of the growth rate in industrial production is interacted with *Flexibility*, the coefficient on *Flexibility* remains significant at the 5% level in both the employment and participation regressions (equal to 0.056 and 0.065, respectively). Regressions (5) and (6) test robustness using the change in openness (as our proxy for industrial turbulence) with similar results.

### 3.4. Other hypothesis on the consequences of labor market flexibility

Following the work of Davis and Haltiwanger (1990), there has been growing interest in the profession on the empirical behavior of job creation and job destruction. We were unable to obtain comparable cross-country measures of these variables. We did, however, obtain a measure of unfilled vacancies divided by total employment from the CEP-OECD data set (that in turn collects it from the OECD main economic indicators)

<sup>19</sup> All results reported in the paper but not included in the tables are available on request.

which is as close as we can get to a measure of job creation. And Pascal Marianna at the OECD kindly provided us with the unpublished data for inflows revised in 1998.<sup>20</sup> In Table 8A and B, we study the effect of flexibility on these variables. In spite of some inconsistencies, the results are interesting. For example, regression (1) in Table 8A shows that the pooled data reveal a very strong positive association between inflows and flexibility. However, estimation by random effects makes the coefficient insignificant (and negative). In fact, when country dummies are included in regression (3) the effect of flexibility on inflows is negative and significant. This result does not survive re-estimation with robust regression techniques or the inclusion of year dummies in regression (4).

Regression (5) shows low persistence of inflows and some positive effects of unemployment benefits. The last two regressions in Table 8A control for the state of the business cycle (proxied by the change in *GDP*). As expected there are fewer inflows during expansions. Regression (7) examines if the evidence supports the hypothesis that the relationship between the business cycle and inflows is affected by flexibility by including an interaction term ( $\Delta GDP * Flexibility$ ). The estimated interaction effect has the expected sign but is insignificant. With respect to vacancies, there are again some inconsistencies. Regression (4) in Table 8B shows that, controlling for both country and time fixed effects, countries with higher levels of labor market flexibility have less unfilled vacancies.<sup>21</sup> Presumably, this indicates that in flexible labor markets vacancies are filled more quickly. In regression (6) we find that, somewhat reassuringly, there are more vacancies in a recovery and that there are well-defined negative effects of flexibility on vacancies. Column (7) shows that there are more vacancies in a recovery that occurs in a country with high flexibility (due to the positive interaction term).

Lastly, in Table 9 we examine two other hypotheses that have been proposed in the literature. The first is the jobless recovery hypothesis; the idea that in more inflexible labor markets Okun's law has to be adjusted downwards. Bertola 1990 shows that cross-section evidence is consistent with this view. In order to examine the evidence on these issues, we present regressions (1) and (2) in Table 9 where the dependent variable is the change in the unemployment rate. Regression (1) shows the basic relationship between  $\Delta Unemployment$  and  $\Delta GDP$ , once we control for country and time fixed effects. Regression (2) shows that the interaction term ( $\Delta GDP * Flexibility$ ) is negative and significant at the 10% level, indicating that when *GDP* increases, unemployment falls more in countries with more flexible labor markets.

Second, we test the hypothesis that unemployment persistence is greater in countries with more inflexible labor markets. This hypothesis has been suggested, in one form or another, by Blanchard and Summers (1986) and Lindbeck and Snower (1989). It is also examined in Bertola (1990) who finds evidence consistent with this hypothesis. To test this proposition, we allow for the coefficient on the lagged dependent variable in standard unemployment regressions to vary with the degree of flexibility. In Table 9,

<sup>20</sup> We interpolated four values of inflows, Netherlands 1984 and 1986 and Finland 1988 and 1990. The results do not change if these observations are excluded.

<sup>21</sup> Normalizing by unemployment (instead of employment) produces largely similar results.

regression (3) includes an interaction term,  $Unemployment_{t-1} * (1 - Flexibility_{t-1})$ , which is positive and significant at the 2% level.<sup>22</sup> In other words, more inflexibility (i.e. corresponding to greater values of  $1 - Flexibility_{t-1}$ ) is associated with a larger coefficient on the lagged dependent variable. Using the coefficients of regression (3), the United States would have a coefficient on lagged unemployment of  $0.596 + 0.462 * (1 - 0.727) = 0.72$ , ceteris paribus (mean flexibility over the sample period equals 0.727 in the US). On the other hand, France would have a coefficient on lagged unemployment of  $0.596 + 0.462 * (1 - 0.423) = 0.86$ , ceteris paribus (mean flexibility over the sample period equals 0.423 in France). Furthermore, as we move from the most flexible country in the sample (the US) to the least flexible country (Spain), the coefficient on lagged unemployment is estimated to rise from 0.72 to 0.92 ( $= 0.596 + 0.462 * (1 - 0.298)$ , since mean flexibility over the sample period equals 0.298 in Spain). Regression (4), which is estimated using GMM, shows a similar effect, with the interaction term again positive and significant at the 2% level. The effect on the coefficient of lagged unemployment of changing the level of flexibility is now larger than in regression (3). A decrease in flexibility equivalent to a shift from the US to France is expected to add 0.25 ( $= 0.820 * (0.727 - 0.423)$ ) onto the size of the coefficient on lagged unemployment. Thus, the evidence is consistent with the hypothesis of Blanchard and Summers (1986), and Lindbeck and Snower (1989), as there seems to be less unemployment persistence in flexible labor markets.<sup>23</sup>

#### 4. Conclusion

One of the biggest challenges in economics today is to explain what causes unemployment. Economists who study European unemployment often point out that it must be labor market regulations. This view has been adopted by international institutions like the World Bank and the IMF, which now insist that countries make their labor markets more flexible when providing them with financial support. The evidence available to support this view consists of cross-sections, like that of Bertola (1990) with 10 countries, or the OECD (1994) with 21, and the panel constructed by Lazear (1990). Because the latter focuses on laws for two aspects of flexibility that change little over time, these data are almost like another cross-section. There is, perhaps, no experience more sobering to an economist than to review the evidence we have to support policy recommendations on labor market flexibility and to reflect on the social, economic and personal costs of unemployment.

We introduce a new panel data set on labor market flexibility based on surveys of business people in 21 OECD countries during 1984–1990. One of the virtues of the data is that they originate from people who have to make their living out of roughly understanding how stringent job security provisions actually are in their countries. The

<sup>22</sup> This regression is illustrative. Caution should be exercised when using the absolute values of these coefficients because of the bias in short panels with lagged dependent variables.

<sup>23</sup> Furthermore, the argument that managers' responses to the flexibility survey question may depend on the stage of the business cycle would not seem to be able to explain this persistence effect.

use of a subjective index allows respondents to capture movements in very different kinds of regulations that affect the flexibility of labor markets, such as provisions on part time work, severance payments, interpretation (and enforcement) of what constitutes legal cause for termination and so on. These regulations imply very different costs to normal business operations and would be extremely difficult to document with hard data. There are, of course, limitations to the data we use. The index is more vague than what an economist would ideally like to use. By its nature, our flexibility index does not allow us to distinguish between the effect of the different regulations that are active. And although we present some time series/cross-section validation exercises, the fact must remain that data that are subjective in nature must be treated with care. However, we believe the relevance of the subject matter and the evidence available to the profession to be so out of balance that a willingness to experiment with survey data is justified.

We follow Lazear (1990) and use a parsimonious, reduced form approach to study the effect of flexibility on labor market performance. Our main findings are:

1. Controlling for country and time fixed effects, and using dynamic panel data techniques developed by Arellano and Bond (1991), we find that countries with more flexible labor markets have higher employment rates and higher rates of participation in the labor force. The results on employment are inconsistent with Bentolila and Bertola (1990) and Bertola (1990) and are consistent with the predictions in Hopenhayn and Rogerson (1993).
2. These results are stronger in the female labor market, although the long-run effects are approximately similar across both male and female sub-groups.
3. A potential drawback of these data is their contamination by the stage of the business cycle. When the economy is in recession firms are more likely to be firing than hiring and so employment protection legislation may impose binding constraints on firms. If managers' responses to our survey question were in fact in the direction of greater inflexibility at such times, even though the parameters of the system have not changed, then the interpretation of our results would be different. Consequently, we repeated all our regressions controlling for the state of the business cycle (the change in *GDP*). The results are unaffected. We also note that it would be hard to explain some of our coefficients if the contamination of the flexibility data with the business cycle was the main factor driving our results.
4. The estimated employment effects seem to be large. A conservative estimate is as follows: if France were to increase the flexibility of its labor markets to US levels, the employment rate would increase by 1.6 percentage points, almost 14% of the actual difference in employment rates between the two countries. In order to estimate the effect of flexibility on French *GDP* per capita, we note that this increase in flexibility would lead to a 2.8% increase in French total employment. Of course, this says nothing about the convenience of such a reform. For that we would need information on the benefits (in terms of employment security, wages and so on) of flexibility, a fact sometimes forgotten in policy debates.
5. The paper only finds some evidence that countries with more flexible labor markets have lower unemployment rates and a lower proportion of long term unemployed.

The problem of the endogeneity of labor market institutions is addressed but still must remain an open issue.

6. In spite of some inconsistencies, the results on inflows and vacancies are interesting. Controlling for country and year fixed effects, we do not find evidence of positive effects of flexibility on inflows. We do however find evidence that more flexibility is associated with lower rates of unfilled vacancies and that there are more vacancies in a recovery that occurs in a country with high flexibility.
7. Lastly, we explore some alternative hypotheses related to flexibility that have been suggested in the literature. First, we examine the jobless recovery hypothesis. We find evidence that Okun's law is steeper in countries with very flexible labor markets (as suggested in Bertola, 1990). We also find evidence consistent with a second hypothesis tested by Bertola and suggested by Blanchard and Summers (1986) and Lindbeck and Snower (1989): that the dynamic structure of unemployment regressions is affected by flexibility. Controlling for country and time fixed effects, we find that unemployment is less persistent in countries with more flexible labor markets.

## Acknowledgements

We thank the editor (Jordi Gali) and two anonymous referees for helpful suggestions. We also give thanks to Andrew Oswald, Alberto Ades, Danny Blanchflower, Steve Bond, Lawrence Katz, Sebastian Galiani, Guillermo Mondino, Pascal Marianna, Edmund Phelps, Julio Rotemberg, Jürgen von Hagen as well as seminar participants at Deutsche Bundesbank, Dartmouth, IEA, Harvard, Oxford and Bonn.

## Appendix A

### A.1. Sample of 21 countries

Australia, Austria, Belgium, Canada, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Japan, Netherlands, New Zealand, Norway, Portugal, Spain, Sweden, Switzerland, United Kingdom, United States.

### A.2. Definition of the variables

*Employment*: Total civilian employment divided by the population aged between 15 and 64 years old. From the updated CEP-OECD data set.

*Male employment*: Total civilian male employment divided by the population aged between 15 and 64 years old. From the updated CEP-OECD data set.

*Female employment*: Total civilian female employment divided by the population aged between 15 and 64 years old. From the updated CEP-OECD data set.

*Participation*: Total civilian employment plus total unemployment divided by the population aged between 15 and 64. From the updated CEP-OECD data set.

*Male participation*: Total civilian male employment plus total male unemployment divided by the population aged between 15 and 64. From the updated CEP-OECD data set.

*Female participation*: Total civilian female employment plus total female unemployment divided by the population aged between 15 and 64. From the updated CEP-OECD data set.

*Unemployment*: The unemployment rate, defined as the total number of unemployed workers divided by the total number of both employed and unemployed workers, from OECD Historical Statistics (1997).

*Long-term unemployment*: The number of workers who have been out of work for 6 months and more as a percentage of total unemployment, from the OECD Employment Outlook (1985–1991).

*Benefits*: The OECD summary measure of parameters of the UI system. To calculate this measure, the situation of a representative individual is estimated using their unemployment benefit entitlements divided by the corresponding wage. Consequently, the unweighted mean of 18 numbers based on the various combinations of the following scenarios is determined (1) three unemployment durations (for persons with a long record of previous employment)—the first year, second and third years, and fourth and fifth years of unemployment, (2) three family and income situations: a single person, a married person with a dependent spouse, and a married person with a spouse in work; (3) two different levels of previous earnings – average earnings and  $\frac{2}{3}$  of average earnings (see OECD Jobs Study, 1994).

*Flexibility*: The survey question that we use (classified as 2.17 *LABOR-COST FLEXIBILITY* in 1984) asked the respondents: “*Flexibility of enterprises to adjust job security and compensation standards to economic realities: 0 = none at all, to 100 = a great deal*”. This question was changed in 1990 to “*Flexibility of management to adjust employment levels during difficult periods: 0 = low, to 100 = high*”. From the WCR, EMF Foundation, Cologne/Geneva.

*Inflow rate*: Number of people unemployed less than one month divided by the employed. Updated by the OECD in 1998. Unpublished.

*GDP*: The log of total *GDP* expressed in constant 1985 prices, from the updated CEP-OECD data.

*Openness*: Exports over *GDP* from the updated CEP-OECD data set.

*Industrial production*: The log of the total value added in industry expressed in constant 1985 prices, from OECD Historical Statistics (1997).

*Service sector*: The log of the total value-added in the service sector expressed in constant 1985 prices, from OECD Historical Statistics (1997).

*Employment taxes*: Employers’ total employment tax contributions divided by the total compensation of employees (net of employment taxes), from the updated CEP-OECD data set.

*Terms of trade*: Ratio of average value of exports to average value of imports (from OECD Historical Stats).

## Appendix B

Description of various data for 21 countries for the period 1984–1990 are given in Table 1 and correlation between flexibility and indicators of business cycle (1984–1990) is given in Table 2.

Table 1  
Description of the data: 21 Countries, averages for 1984–1990

<i>Country</i>	<i>Flexibility</i>	<i>Benefits</i>	<i>Employment</i>	<i>Unemployment</i>	<i>LTU</i>
Australia	38.45	0.24	0.66	0.08	0.47

## Appendix C

Determinants of the employment rates of 21 OECD countries for the period 1984–1990 are given in Table 3. Determinants of different participation rates for 21 countries (1984–1990) are given in Table 4. Table 5 describes unemployment rates for these countries for the same period. For these countries, Table 6 estimates casualty and non-linear effects, random effect and fixed effects. Table 7 describes determinants of employment and participation, controlling for response bias. Table 8 describes inflow rate and vacancies, while Table 9 gives Okun's law and unemployment persistence.

**The Cost of Job Security Regulation:  
Evidence from Latin American Labor Markets<sup>1</sup>**

James Heckman

Carmen Pagés  
Inter-American Development Bank

Revised draft: May 2000

---

<sup>1</sup> We thank Ricardo Caballero, Alexandra Cox-Edwards, Pablo Guidotti, Tom Miles, Andres Velasco and participants in the LACEA Conference, NYU, New York, May 2000, for their comments on a previous draft. We also thank Marianne Hilgert and Ricardo Fuentes for excellent research assistance. This paper is forthcoming in the first issue of the LACEA journal "Economía." Heckman's research on this project was supported in part by the American Bar Foundation.

## 1. Introduction

Labor market regulations are introduced with the stated objective of improving workers' welfare. Mandated benefits and social security programs improve workers' income security in case of sickness, work accidents and old age. Job security provisions are designed to reduce a worker's odds of losing her job and her means of living. But, as is often true in economics, benefits usually come at a cost: mandated benefits may reduce employment; job security provisions may protect some workers at the expense of others.

This paper gathers evidence from existing and new sources of information on the costs of job security policies. Latin America has experienced a wide range of labor market policies that provide natural experiments with which to evaluate the impact of these policies. Our evidence challenges the prevailing view (see e.g. Abraham and Houseman (1994), Blank and Freeman (1994), Freeman (2000) and the papers he cites) that labor market regulations do not affect employment and have minimal costs. We establish that job security policies have a substantial impact on the level and the distribution of employment in Latin America. The evidence for their effect on unemployment is much weaker but there are good conceptual reasons why this should be so.

Our focus on the cost side does not imply we believe the benefits of labor policies for protected workers are small or irrelevant. While the benefits to recipients are well-documented, the costs are often unintended and less well understood. Thus, while the evidence suggests that regulations promoting job security reduce covered workers exit rates out of employment, it also indicates that demand curves are downward sloping, that regulation reduces aggregate employment and that the greatest adverse impact of regulation is on youth and groups marginal to the workforce. Insiders and entrenched workers gain from regulation but outsiders suffer. As a consequence, job security regulations reduce employment *and* promote inequality across workers.

The outline of the paper is as follows. Section 2 describes and quantifies job security regulations in Latin America and the Caribbean. In section 3, we summarize the existing evidence on the impact of job security provisions on employment, unemployment and turnover rates in Latin America. Section 4 presents new evidence. In section 5 we summarize the paper and present our conclusions.

## 2. Job Security Regulation in Latin America and the Caribbean

In this paper, we define job security legislation (JS) to include all those provisions that increase the cost of dismissing a worker. In this section, we quantify the costs of abiding by the legislation, in terms of wages, in order to address three questions: (1) How high are the implied costs of JS provisions in Latin America and the Caribbean? (2) Within the region, which countries have costlier termination provisions and which are more deregulated? (3) How do Latin American and Caribbean countries compare with industrial countries in terms of JS legislation?

In Latin American countries, labor codes based on the civil law system regulate the permissible types, durations and the conditions for termination of labor contracts. In contrast, most Caribbean countries are based on the common law system so the law enforces a contract with which both parties privately agree. As a consequence, in some countries there is not a specific body of law regulating employer-employee relationships, while in others some aspects are regulated while others are left to the courts.

In Latin America, labor codes favor full-time indefinite employment over part-time, fixed-term or temporary contracts. These types of contracts not only differ in the length of the employment relationship but also in the conditions for termination. While indefinite contracts carry severance pay obligations, temporary contracts can be terminated at no cost provided that the duration of the contract has expired. In contrast, most Caribbean countries do not regulate the range of admissible contracts. Instead, such decisions are left to the parties involved in collective bargaining.

There are important differences as well in the conditions for termination of contracts. In Latin America, the termination of a contract is severely restricted. Thus, labor codes mandate a minimum advance notice period prior to termination, determine which causes are considered “just” or “unjust” causes for dismissal, and establish compensation to be awarded to workers for each possible cause of termination. In some countries, firms must also request permission to dismiss more than a certain fraction of their labor force. Finally, some countries allow the reinstatement of a worker to her post if the dismissal is found to be “unjustified” by the courts, although, this provision has been eliminated in many countries. In contrast, in

some of the Caribbean countries, advance notice and severance pay are negotiated as part of collective agreements, so there are no specific laws regulating such provisions.

Termination laws (or collective agreements) require firms to incur four types of costs: advance notification, compensation for dismissal, seniority premium for dismissed workers and foregone wages during any trial in which the worker contests dismissal. The period of advance notification should be included in the computation of costs because, in general, the various laws typically allow firms to choose between providing advance notice or paying a compensation equivalent to the wage corresponding to that period. Moreover, since productivity can decline substantially after notice, advance notification should be considered as a part of the dismissal cost even when firms choose to notify workers in advance. Advance notification periods vary from country to country, ranging from zero in Nicaragua, Guatemala, Peru and Uruguay to three months in Bolivia, Haiti and Venezuela for workers with more than 10 years at a firm (See Table 1.A in the Appendix).

The second component of dismissal cost is compensation for unjustified dismissal. Since in most Latin American countries the economic difficulties of a firm are not considered a just cause for dismissal, any labor force reductions fall in this category. The formula for calculating this compensation is based on multiples of the most recent wage and the years of service. In contrast, in the Caribbean, under union agreements, severance pay is only awarded to a worker in the case that a firm needs to reduce the work force for lack of work or technological change. In most other cases, employment at will is still the norm provided that the firm gives reasonable advance notice to a worker. Finally, in Belize, Bolivia, Chile and Nicaragua, the law mandates compensation to the worker in case of a voluntary quit<sup>2</sup>.

In some countries, employers are required to make an additional payment, known as a seniority premium, upon termination of the work relationship regardless of the cause or party initiating the termination. In Ecuador, Colombia, Panama, Peru, and Venezuela, this benefit is available to the worker both in the case of unjustified dismissal and in the case of a voluntary quit. If a worker quits, she obtains this payment, whereas if the worker is dismissed she obtains this payment *plus* the compensation for dismissal. In Brazil, this additional payment is only available in the case of unjust dismissal, and if the worker quits, she receives no pay. In all the above-mentioned countries, firms deposit a certain fraction of

---

<sup>2</sup> In Chile, compensation in case of a quit only occurs after the 7<sup>th</sup> year of service and if the worker chooses to set up an account.

workers' monthly wages in an individual trust fund in order to provide for this payment.<sup>3</sup> In Ecuador, Colombia, Brazil and Peru, the worker gains access to the principal plus a yield.<sup>4</sup> In Panama and Venezuela, the seniority premium is fixed in terms of multiples of monthly wages and the amount accrued in the fund (Panama) or the fund plus a certain yield (Venezuela) pays for the seniority premium. However, the firm is responsible for covering the difference between the required seniority premium and the amount accumulated in the seniority premium fund.

Finally, in some countries, firms are also required to pay a worker's foregone wages during the period of any legal process if a worker brings an action against the firm. This provision increases the overall cost of termination by either increasing the overall compensation due and/or reducing workers' incentives to settle out of court.<sup>5</sup>

During the nineties, seven countries (Colombia, Guyana, Guatemala, Nicaragua, Panama, Peru, and Venezuela) reformed their labor codes in order to reduce the cost of dismissing a worker. Not all labor reforms reduced JS, however. In Chile (1991) and in Dominican Republic (1992), the amount that a firm has to pay upon dismissal of a worker increased considerably during the nineties.

In an attempt to quantify all of these provisions we construct an index of JS encompassing LAC and industrial countries. There have been previous attempts to construct such types of measures. Bertola (1990), Grubbs and Wells (1993) and the OECD (1993, 1999) constructed ordinal measures of JS for industrial countries whereas Marquéz (1998) constructed ordinal measures of job security for a sample of industrial and LAC countries. Also, Lazear (1990) quantified firing costs as the amount (in multiples of monthly wages) owed to a worker if she is dismissed after 10 years of service. These measures, however, are unlikely to accurately reflect the magnitude of dismissal costs.

On the one hand, ordinal measures can only state that one country is more regulated than another, but cannot measure how much more regulated it is. On the other hand, JS tends to increase in tenure, which implies that measures conditional on certain level of tenure only measure a given point in the severance-tenure schedule. To address these shortcomings, we construct an alternative cardinal measure of firing costs that summarizes the entire tenure-severance pay profile using a common set of dismissal probabilities

---

<sup>3</sup> In Brazil, the fund is called FGTS, in Peru, CTS, in Colombia, *Fondo de Cesantia* and in Panama, *Fondo de Antigüedad*.

<sup>4</sup> In Brazil a worker gets access to this fund only if she is dismissed.

across countries. This measure computes the expected future cost, at the time a worker is hired, of dismissing her in the future due to unfavorable economic conditions.<sup>6</sup> The index is constructed to include only firing costs that affect firm's decisions at the margin and therefore it does not include the full cost of regulation on labor demand. It includes the cost of providing statutory advance notice and severance pay conditional on each possible level of tenure that a worker can attain in the future.

The JS index does not include the seniority premium as part of cost because, in most countries, provisions for that payment are regularly deposited in a fund. Thus, because deposits are not directly made conditional on a dismissal they are not likely to alter firing decisions. Rather they should be treated as other labor costs incurred by the firm that do not affect firing decisions and are not included in our index. However, they clearly affect the cost of labor to the firm. The index also does not include the cost derived from foregone wages during trial. Although this component may be a substantial share of the total of cost of dismissal, we do not include it in our index because the information on this cost is not available. Thus we cannot estimate the full cost of resolution of legal costs arising from challenges to dismissals through the courts.

Our measure of JS thus reflects the marginal costs of dismissing full-time indefinite workers. However, this measure does not capture the effects of recent reforms that have made temporary and fixed-term contracts widely available in countries like Argentina and Peru. To the extent that fixed-term and indefinite contracts are not perfect substitutes—since temporary workers may be less productive (see the evidence in Aguirragabiria and Borganso, 2000)—our index still captures the marginal cost of firing a tenured worker. However, firms may be at the margin of firing temporary workers and so our index overstates the true marginal cost. Additional information regarding the construction of this index can be found in the Appendix. This measure will be used in Section 3 to quantify the impact of JS on different employment and unemployment measures in a sample of OECD and LAC countries.

Graph 1 displays the costs of advance notice and compulsory severance pay in Latin American and the Caribbean for 1990 and 1999 as summarized by our index. This graph reveals that even after many countries have reduced dismissal costs during the nineties, the average cost of dismissing a worker is still

---

<sup>5</sup> Another component of dismissal costs that can be quite important in some countries is given by the specific regulations that govern collective dismissals. Information on those regulations is not available for most countries of LAC and therefore we did not include them in our discussion or measurements.

higher in Latin America than in our sample of industrial countries. In comparison, the countries of the Caribbean basin exhibit much lower dismissal costs.

Table 1: Job Security Index across Latin America, the Caribbean and OECD countries.  
End of the nineties

<i>Country</i>	<i>Index Job Security (Monthly wages)</i>	<i>% Annual wage</i>	<i>Ranking</i>

Source: Authors' computations (See Appendix)

<sup>6</sup> This measure is based on the index developed in Pagés and Montenegro (1999)

Looking at the individual countries, it may be surprising that countries like Argentina or Mexico exhibit lower JS than Chile, a country traditionally considered as having a more flexible labor market. This divergence is caused by the fact that our index only measures one component of labor market rigidities. So while Argentina and Mexico have stronger unions than Chile, and therefore are likely to have higher wage rigidity, Chile has higher individual job security provisions. Our index, also discounts penalties that arise far in the future, and so the fact that labor codes in Chile and other countries establish an upper limit in payments is discounted in our measure.

Graph 1 shows that four countries in Latin America (Nicaragua, Venezuela, Panama and Peru) undertook substantive reforms in their labor codes. Nicaragua and Venezuela reduced the expected dismissal cost by more than three monthly wages, while Panama and Peru reduced it between one and one and half monthly wages. However, Table 1 also makes clear that even after a decade of substantial deregulation, Latin American countries remain at the top of the JS list, with levels of regulation similar to or higher than those existing in the highly regulated South of Europe. We next consider quantitative estimates of the impact of job security regulations.

### **3. The impact of job security regulations**

The goal of this section is to quantify the impact of job security regulations on employment and turnover rates. The importance of dismissal costs in Latin America is clear in Graph 1. It is thus important to assess the impact, if any, that such policies have on the labor market.

#### **3.1 Theoretical discussion**

To analyze the impact of job security provisions requires a more complex framework that encompasses dynamic decisions of firms. Bertola (1990) develops a dynamic partial-equilibrium model to assess how a firm's firing and hiring decisions are affected by dismissal costs. In the face of a given shock, the optimal employment policy of a firm involves one of three state-contingent responses: (i) dismissing workers, (ii) hiring workers and (iii) doing nothing, in which case employment in that firm does not change. How are these decisions altered by firing costs? In the face of a negative shock and declining marginal value of

labor, a firm may want to dismiss some workers, but it has to pay a mandatory dismissal cost. This cost has the effect of discouraging firms from adjusting their labor force, resulting in fewer dismissals than in the absence of such costs. Conversely, in the face of a positive shock firms may want to hire additional workers but will take into account that some workers may have to be fired in the future if demand turns down, and this is costly. This prospective cost acts as a hiring cost, effectively reducing creation of new jobs in good states. The net result is lower employment rates in expansions, higher employment rates in recessions and lower turnover rates as firms hire and fire fewer workers than they would in the absence of these costs.

Bertola's model predicts a decline in employment variability associated with firing costs but the implication of his model for average employment is ambiguous. In particular, whether average employment rates increase or decline as a result of firing costs depends on whether the decline in hiring rates more than compensates the reduction in firings. Indeed, simulations reported in Bertola (1990) and Bentolila and Bertola (1990) suggest that average employment (in a given firm) is likely to increase when firing costs increase. These results, however, are quite sensitive to different assumptions about the persistence of shocks, the elasticity of the labor demand, the magnitude of the discount rate, and the functional form of the production function. Thus, less persistent shocks and lower discount rates are associated with larger negative effects of JS on employment because both factors reduce hiring relative to firing (Bentolila and Saint Paul, 1994). Furthermore, a higher elasticity of the demand for goods implies a larger negative effect of job security on employment rates (Risager & Sorensen, 1997). In addition, when investment decisions are also considered, firing costs lower profits and discourage investment, increasing the likelihood that firing costs reduce the demand for labor (Bertola, 1991).

The results just reported analyze employment rates in one firm without considering the impact of firing costs on the extensive margin, that is, on how firing costs affect the creation and destruction of firms. Hopenhayn and Rogerson (1993) develop a general equilibrium model based on the U.S. economy that accounts for entry and exit of firms. In their model, the partial equilibrium framework of Bertola (1990) is embedded in a general equilibrium framework in which jobs and firms are created and destroyed in every period in response to firm-specific shocks. In the context of their model, they find that increasing firing costs in the U.S. would lead to an increase in the average employment of existing firms as a consequence of the reduction in firings. However, they also find that such a policy would result in lower firm entry, and

lower job creation in newly created firms. For the parameter values they consider, these two last effects offset the increase in employment in existing firms resulting in a reduction of overall employment rates.

Job security may also affect employment through its effect on wages. The insider/outsider literature emphasizes that job security provisions increase the insider power of incumbent workers. This effect results in higher wages for insiders and lower overall employment rates (Lindbeck and Snower, 1987b). Caballero and Hammour (1997) consider a model in which job security provisions increase the *appropriability* of capital by labor by increasing capital specificity. That is, a larger part of the capital invested becomes relationship specific and becomes lost if capital separates from labor. While in the short-run, higher firing costs allow labor to extract higher rents from capital, in the long-run firms invest in less labor intensive technologies, reducing employment demand.

Some recent literature has also emphasized the possible impact of job security regulations on the composition of employment. Kugler (2000) proposes a model in which job security regulations provide incentives for high turnover firms to operate in the informal sector. This decision entails producing at a small, less efficient scale in order to remain inconspicuous to tax and labor authorities. In this framework, high job security is likely to increase informality rates. Pagés and Montenegro (1999) develop a model in which JS related to tenure biases employment against young workers and in favor of older ones. As severance pay increases with tenure, and tenure tends to increase with age, older workers become more costly to dismiss than younger ones. If wages do not adjust appropriately, negative shocks result in a disproportionate share of layoffs among young workers. Therefore, job security based on tenure results in lower employment rates for the young, relative to older workers, because it reduces hiring and *increases* firings for young workers.

We conclude that higher JS provisions reduce turnover rates and bias the composition of employment against young workers and against employment in the formal sector. The implications for average employment in the economy at large are, however, somewhat less conclusive since they can depend on specific configurations of parameters for the economy. To complicate matters further, by the Coase theorem the impact of job security could be completely “undone” with a properly designed labor contract provided that there are no restrictions on transactions between workers and firms. (Lazear, 1990). Thus, in a world without transactions costs, wages adjust to offset the possible negative impact highlighted

in the previous discussion. Given the ambiguity of theoretical models, the magnitude and direction of the impact of job security on employment has to be resolved empirically. In the following two subsections, we discuss existing evidence relating JS to labor market outcomes and present some new evidence of our own.

### **3.2. Empirical Evidence for Latin America and the Caribbean**

Despite the existence of strict job security regulation in most of the countries of the region, research assessing its impact has been extremely scarce. Fortunately, a recent series of empirical studies assess the impact of job security regulation on employment and turnover rates in Latin America and the Caribbean providing the first systematic evidence of its impact on the labor market.<sup>7</sup> Several studies assess the impact of job security on turnover rates in the labor market. Changes in turnover are measured using changes in the duration of jobs (tenure), the duration of unemployment and the exit rates out of employment and unemployment.<sup>8</sup> Higher employment exit rates indicate more layoffs (or more quits), while higher exit rates out of unemployment and into formal jobs indicate higher job creation in the formal sector. Other studies examine the impact of job security on employment rates. The definition of employment changes depending on the data considered. In general, most studies focus on employment in large firms, although some also examine more aggregated measures of employment. In addition, a small group of studies also examines the impact of job security on the composition of employment (See Table 2 for an overview of the empirical evidence for Latin America and the Caribbean).

#### **A. Turnover Rates**

The strongest evidence is on the impact of job security on turnover. As predicted by most theoretical models, the empirical evidence confirms that less stringent job security is associated with higher turnover in the labor market. Kugler (2000) analyzes the impact of the 1990 labor market reforms in Colombia. She finds that a reduction in job security is associated with a decline in average tenure and an increase in employment exit rates.<sup>9</sup> This decline is significantly larger in the formal sector that is covered by the regulations than in the uncovered or informal sector. In addition, the increase is larger in large firms

---

<sup>7</sup> Most of these projects were developed under the IDB research network project “Labor Market Legislation and Employment in Latin America” coordinated by J. Heckman and C. Pagés.

<sup>8</sup> These studies estimate hazard rates. The hazard rate is defined as the probability that a given spell of employment or unemployment ends in a given period conditional on having lasted a given period of time (e.g., one month, one year).

and imprecisely determined in the smallest ones. Her results shows similar patterns within tradable and non-tradable sectors, providing a clear indication that the decline in tenure cannot be attributed to contemporary trade reforms. The increasing use of temporary contracts explains only part of the increase in formal sector turnover rates since job stability also declined for workers employed at permanent jobs.<sup>10</sup> Her results also indicate that the increase in turnover is larger for those workers who are more protected by high levels of job security, that is the middle aged and older men employed in large firms.

Kugler also finds a decline in the average duration of unemployment after the reforms. In addition, exit rates out of unemployment increase more for workers who exit to the formal sector than they do for those who exit to informal jobs. Her results show quite similar patterns across sectors and a higher exit rate towards larger firms. Finally, only two-thirds of the increase in the rate of entry into employment can be attributed to higher use of temporary contracts: the rest is explained by increased exit rates into permanent jobs in the formal sector. Her results for different workers suggest that the young and women benefit more from higher exit rates out of unemployment and into the formal sector.

The magnitudes of the estimated effects are not negligible. Kugler estimates that after the reform, the increase in probability of exiting employment was 6.4% larger for covered workers than for uncovered ones while the exit rates out of unemployment and into formal jobs increased by 5.9% with respect to exit rates to the informal sector.

Saavedra and Torero (2000) conduct a similar study, evaluating the impact of the 1991 reform in Peru. Like the reform in Colombia, the 1991 reform considerably reduced the cost of dismissing workers. Their analysis shows a consistent decline in average job tenure from 1991 onwards suggesting higher employment exit rates. As in Colombia, the decline is significantly more pronounced in the formal than in the informal sector, but the magnitude of the fall is larger in Peru. Finally, tenure patterns are also quite similar across economic sectors, suggesting that these findings cannot be explained by the far-reaching trade reforms that took place in that country in the early nineties.

Finally, Paes de Barros and Corseuil (2000) provide further evidence from Brazil. Their study estimates the impact of the 1988 Brazilian Constitutional reform on employment exit rates. In that year, the

---

<sup>9</sup> In this study tenure is measured by the duration of incomplete spells.

<sup>10</sup> In her study, Kugler performs two types of analysis. First, she uses a difference-in-difference estimator to analyze whether changes in average duration of employment (unemployment) are statistically significantly different in the formal than in the informal sector.

cost of dismissing workers was raised and therefore a reduction in exit rates would be expected. Their results confirm that aggregate employment exit rates decline in the formal sector relative to the informal sector for long employment spells (two years or more).

The credibility of these studies hinges on the validity of the informal sector as a control group unaffected by the reforms. Kugler (2000) shows that while estimates based on formal-informal sector comparisons are likely to be biased, under plausible conditions, such comparisons are still valid, at least as tests of the null hypothesis of no effect of the reform.<sup>11</sup> When taken together, these studies provide consistent evidence that dismissal costs and other employment protection mechanisms reduce worker reallocation in the labor market. Unfortunately, these studies do not identify whether increased worker reallocation is due to increased layoffs, higher quits or a mix of both.

Hopenhayn (2000) provides further evidence of the link between JS and worker turnover rates in Argentina. In 1991, the government of Argentina deregulated the use of temporary and fixed-term short-duration contracts. In 1995, additional contractual forms were allowed including a three-month trial period. Such contracts reduced or eliminated the cost of terminating an employment relationship. Hopenhayn (2000) finds that after 1995, employment exit rates increase substantially for short employment duration while they remain constant for long durations. This increase in separations is due to a rise in both quits and layoffs, although the increase in layoffs is higher.

Summarizing, the evidence provided in this section indicates that JS regulations protect workers against the risk of losing a job. From this point of view, the recent reforms have reduced the income security of formerly protected workers. However, the evidence also suggests that stringent JS provisions reduce exit rates out of unemployment and into formal jobs, thus prolonging the duration of unemployment. Thus, recent labor market reforms have increased the probability of an unemployed worker finding a job in the formal sector.

---

Second, she estimates an exponential duration model to control for changes in demographic covariates, pooling data from before and after the reform and using interaction terms to assess the differential impact in the formal and in the informal sector.

<sup>11</sup> Kugler shows that lower severance pay may induce high-turnover informal firms to move to the formal sector. Under the assumption of no overlap in the distribution of turnover between covered and uncovered firms, or that entry to the covered sector comes from the high-end –or at least from the end that is higher than the formal sector--, this shift results in higher turnover in both the

## B. Average Employment

The available evidence for LAC countries shows a consistent, although not always statistically significant, negative impact of JS provisions on average employment rates. Saavedra and Torero (2000) and Mondino and Montoya (2000) use firm-level panel data to estimate the impact of job security on employment in Peru and Argentina, respectively. Both studies estimate labor demand equations in which an explicit measure of job security appears on the right hand side of the equation, and both find evidence that higher job security levels are associated with lower employment rates.<sup>12</sup> In the case of Peru, Saavedra and Torero find that the size of the impact of regulations is correlated with the magnitude of the regulations themselves. Thus, the impact is very high at the beginning of their sample (1987-1990) coinciding with a period of very high dismissal costs (see Table 1.A). Afterwards, and coinciding with a period of deregulation, the magnitude of the coefficient declines, only to increase again from 1995 onwards, after a new increase in dismissal costs. Their estimates for the long-run elasticities of severance pay are very large (in absolute value): between 1987 and 1990 a 10% increase in dismissal costs, keeping wages constant, is estimated to reduce long-run employment rates by 11%. In subsequent periods, the size of the effect becomes smaller but is still quite large in magnitude (between 3 and 6%). In Argentina, the estimated long-run elasticity of a 10% increase in dismissal costs is also between 3 and 6%.<sup>13</sup>

---

formal *and* the informal sector. Fortunately, higher turnover in the informal sector biases the difference-in-difference estimator downwards. Therefore, a positive estimate still provides substantial evidence of increased turnover in the formal sector.

<sup>12</sup> The data for the Peruvian study covers firms with more than 10 employees in all sectors of the economy. The Argentinean study only covers manufacturing firms. Given the nature of these surveys, they are better proxies for formal employment than for employment as a whole. The data used in these two studies does not capture job creation by new firms, since both panels are based on a given census of firms, without replacement.

<sup>13</sup> While the estimated job-security elasticity in Argentina is much lower (in absolute value) than the wage elasticity reported in Table 2, in the Peruvian case, this elasticity is larger. This is somewhat surprising since job security reduces job creation and *also* slows down employment destruction. Therefore, it might be expected that the JS elasticity would be smaller than the wage elasticity in absolute value. One explanation for the seemingly high elasticity found in the Peruvian study is that this measure is upwardly biased by a simultaneity problem arising from the job security measure. Thus, both the Peruvian and the Argentinean studies construct explicit measures of job security based on:

$$JS_{jt} = \beta_j T_{jt} P_{jt} SP_{jt}$$

Where  $\beta_j$  is the layoff rate in sector  $j$  in sector  $t$ ,  $T_{jt}$  is average tenure in sector  $j$ , time period  $t$ ,  $P_{jt}$  is the share of firms in sector  $j$ , time period  $t$ , that are covered by regulations and  $SP_{jt}$  is the mandatory severance pay in sector  $j$ , given average tenure  $T_{jt}$ . This measure provides variability across sectors and periods, and therefore it affords a more precise estimation of the impact of job security than before-after types of comparisons. Yet, such measure may also be correlated with the error term in a labor demand equation since the tenure structure of a firm might be correlated with its employment level. The fact that average layoff rates vary by sector may also lead to simultaneity if sectors with higher layoffs have lower employment. Thus, periods or sectors with low employment may be associated with less job creation, high average tenure and, consequently, high measures of job security. The Argentinean study shows that fixing tenure to the period average reduces the estimated elasticity of JS. Thus, a JS elasticity between 1/3 and 2/3 of the wage elasticity seems a more realistic estimate of its impact.

**Table 2: Summary of existing evidence on the impact of job security (JS) in Latin America**

<b>A. Studies that analyze exit rates into and out of employment</b>			
<i>Study</i>	<i>Country</i>	<i>Data</i>	<i>Results</i>
Kugler (2000)	Colombia	Household data	Decline in JS leads to reduction in employment and unemployment duration. Also hazard rates out of employment and out of unemployment increase. Some effect due to temporary contracts but not all
Saavedra and Torero (2000)	Peru	Household data	Lower JS is associated with lower average tenure. Higher decline in formal sector. Hazard rates increase just at the end of probation period.
P. de Barros and Corseuil (2000)	Brazil	Employment Surveys, Administrative data and Household surveys	Higher JS associated with a decline in employment exit rates in formal in relation to informal sector.
Hopenhayn (2000)	Argentina	Household data	Deregulation of temporary contracts leads to increase in hazard rates in short but not in long spells
<b>B. Studies that analyze average employment and unemployment</b>			
<i>Study</i>	<i>Country</i>	<i>Data</i>	<i>Results</i>
Downes et al. (2000)	Barbados	Aggregated employment. Annual. It covers large firms (>10 emp)	Negative effect of JS on labor demand (LD). Coeff. Significant at 10%
Saavedra and Torero (2000)	Peru	Firm and sector-level data. Bimonthly 1986-96. Quarterly 1997-98. Formal firms with more than 10 employees. Balanced panel (it does not account for firm creation or destruction)	Negative effect of JS on LD when using sector level-data for whole period. By subperiods, JS has a negative effect from 1987 to 1994, and no effect since then.
Mondino and Montoya (2000)	Argentina	Panel of manufacturing firms. It does not account for firm creation.	Negative effect of JS on LD. The coefficient in unbalanced panels is slightly more negative than in balanced ones.
Kugler (2000)	Colombia	Household data on employment.	Decline in JS in 1990 brings a decline in unemployment rates. Based on computing the net effect of changes in hazard rates, in and out of U induced by the reduction in JS.
P. de Barros and Corseuil (2000)	Brazil	Monthly establishment-level data. 1985-1998 Manufacturing. Firms employing 5 or more workers	Two step procedure. First, find parameters for labor demand (LD) function for every month. Then see whether those parameters change with labor reforms and other development. They find no effect of JS on LD parameters.
Pagés and Montenegro (2000)	Chile	Household data on employment. Annual 1960-1998	Negative but not statistically significant effect of JS on aggregated employment.
Marquéz (1998)	Cross-Country	Cross-section data for Latin America, Caribbean and OECD countries.	Rank indicator of Job Security. JS is not significantly associated with lower employment once GDP per capita is accounted for.
<b>C. Studies that analyze the composition of employment</b>			
<i>Study</i>	<i>Country</i>	<i>Data</i>	<i>Results</i>
Marquéz (1998)	Cross-Country	Cross-section data for Latin America, Caribbean and OECD countries.	Self-employment rates are positively associated with JS even after accounting for differences in GDP per capita.
Pagés and Montenegro (2000)	Chile	Household Survey Data. 1960-1998	JS is associated with lower employment rates for young workers and higher employment rates for older ones. No significant effect on U for young, middle age or older workers.

In a very different type of study, Kugler (2000) computes the net impact of the Colombia 1991 labor reform on unemployment rates. Using unemployment and employment exit rate estimates for periods before and after the reform, she finds that the reforms cause a decline in unemployment between 1.3 and 1.7 percentage points. Thus, as in Mondino and Montoya (2000) and Saavedra and Torero (2000), Kugler's estimates indicate that the positive impact on the hiring margin outweighs the negative impact on the firing margin, resulting in a decline in unemployment rates.

Other studies find negative, but not statistically significant, effects of job security on average employment rates. Pagés and Montenegro (1999) find that JS has a negative but not statistically significant effect on overall wage-employment rates in Chile. Similarly, Marquéz (1998), using a cross-section sample of Latin American and OECD countries finds a negative but not statistically significant coefficient of job security on aggregate employment rates. Table 3 summarizes the various estimates of job security on employment. (The Heckman and Pagés results are discussed below).

Thus, while the theoretical models exhibit some ambiguity regarding the impact of JS provisions on long-run employment rates, the empirical evidence for LAC is consistent across studies. To complement these analyses, we examine two other sources of evidence. First, we review the existing evidence on the impact of JS on employment in OECD countries. Second, in section 4, we provide new evidence combining employment, unemployment and job security measures from a panel of LAC and OECD countries.

**Table 3: Summary of Long- Run JS Elasticities**

<i>Study</i>	<i>Mean</i>	<i>S.E.</i>	<i>Employment Rate</i>
Saavedra & Torero (2000)	-0.406	0.06	Employment in Large firms
Mondino & Montoya (2000)			
High estimate**	-0.684	0.0145	Employment in Large firms
Low estimate***	-0.305	0.0060	Employment in Large firms

Notes: \*Estimates for LAC only. \*\*Based on Table 9, Mondino & Montoya (2000) ,  
 \*\*\*Based on Table 10, option B. Mondino & Montoya (2000)

The evidence from OECD countries reinforces the results found for LA. Thus, with the exception of Anderson (1993), who finds a positive association between dismissal costs and long-run employment, the rest of the studies found a negative impact of JS on employment. Using panel data from OECD countries, Lazear (1990) shows that more stringent job security measures are associated with lower employment and labor force participation rates. Grubb and Wells (1993) find a negative correlation between JS and wage-employment rates. Addison and Grosso (1996) reexamine Lazear's estimates using new measures of job security across countries and find similarly negative effects on employment rates. Nickell (1997) finds a negative effect of JS provisions on total employment rates and no effect on prime-age male employment rates. Finally, a recent OECD (2000) study finds a negative but not statistically significant effect of JS on total employment rates. In contrast, the evidence regarding the effect of JS on unemployment in OECD countries is ambiguous but there are conceptual reasons for being so. While Blanchard (1998), Esping-Andersen (forthcoming), Jackman *et al* (1996) and Nickell(1997) among others find no effect of JS on unemployment, Lazear (1990), Elmeskov *et al* (forthcoming) and Scarpetta (1996) find positive effects. Yet, it should not be a surprise that a negative impact on employment is not necessarily reflected in a positive effect on unemployment. If workers' participation decisions are influenced by JS policies (as shown by Lazear, 1990), a reduction in employment will be associated to a decline in participation rates. This is particularly true for workers with lower attachment to the labor force or with less access to unemployment insurance benefits.

### **C. The Composition of Employment**

Some recent evidence sheds new light on the possible impact of JS on the composition of employment in LAC. Marquéz (1998) constructs a JS indicator for LAC and OECD countries and uses it to estimate the effects of JS on the formal/informal distribution of employment. He finds that more stringent JS provisions are associated with a larger percentage of self-employed workers. In a study of Chile, Pagés and Montenegro (2000) find that more stringent job security is associated with a substantial decline in the wage employment-to-population rates of young workers and an increase in the wage-employment rates of older workers. Their results also suggest that this composition effect is driven by the

high costs of dismissing older workers relative to younger ones created by job security provisions related to tenure.

#### **4. New Evidence**

In this section, we exploit substantial cross-country and time series variability in job security provisions to estimate whether the negative effects of JS encountered in some of the individual-country studies in LAC generalize to a wider sample of countries and reforms.

##### **A. The Data**

We construct a data set that spans industrial and LAC countries. To do so we proceed in two stages. We first collect employment and unemployment data for industrial countries from the OECD statistics. Second, we use the OECD definitions of these variables, to construct the same indicators out of Latin American Household Surveys. Table 4 provides summary statistics for the overall sample, the OECD sample (excluding Mexico, which is included in the LAC sample) and the LAC sample. Table 5 describes the household surveys used to compute the LAC variables. Finally, to characterize job security, we use the index of job security described in section 2.

The number of countries and the average number of observations per country in our sample varies between 36 and 43 countries and between 1 and 5 observations per country, respectively. Among the countries represented, around 28 belong to the sample of OECD countries, while 15 are from the LAC region. Regarding the period spanned in our sample, for most LAC countries, there are one or two observations from the eighties and one or two from the nineties. The OECD sample only covers the nineties. In relation to the variables used in this exercise, it should be noted that all employment rates are measured as a percentage of working age population and all unemployment rates as a percentage of active economic population (See the Appendix for a definition of the variables used in this study)

Table 4 shows some remarkable differences between the OECD and the LAC samples. As noted in section 2, average job security is higher in Latin America and the Caribbean than in OECD countries. In contrast, all employment rates (except for prime-age female employment) are higher and all unemployment rates are lower in the LAC region than in industrial countries. Especially notable are the higher share of

self-employment and the much lower share of long-term unemployment (more than 6 months) in LAC. Finally, union density and female participation are both lower in the LAC region.

## **B. Methodology and Results**

By constructing our own data set from individual household-level surveys, we are guaranteed that all the labor market variables are comparable and reliable. One drawback of our data is that we only have a few time series observations per country (usually three or four), and not necessarily from consecutive years. Given the nature of the data, we decided not to average observations from a given period –as done in most of the OECD studies on job security—and instead control for the state of the business cycle in a given year using GDP growth.

We use a reduced form approach to investigate whether countries and periods with more strict job security regulations are associated with lower employment or higher unemployment rates. Thus we estimate an average net effect of JS as it operates through intermediate variables which we do not include in the regression. In this paper, we do not estimate the theoretically more appropriate state-contingent demand functions because we lack the information on the states of demand confronting individual firms. JS costs govern the marginal costs of labor when firms are firing, but they also affect overall labor demand through their effect on expected (across states) labor cost. It is the latter effect that we attempt to identify. Since most of the variation is cross-sectional, we use different types of variables to control for country-specific factors that may be correlated with job security. First, we use demographic controls such as the share of the population between 15 and 24 and female participation rates. These variables account for the fact that high job security countries in the south of Europe and Latin America tend to have low female participation and a large share of youth population. Since both factors affect overall employment rates, not including them in the specification may lead to substantial biases in the estimates. We protect against common country-specific unobservables that remain constant over time and that may affect both left hand side and right hand side variables by including country-specific fixed effects in a set of regression specifications reported below. Second, we use GDP (measured in 1995 U.S. dollars) to control for

differences in development levels across countries. We also include a dummy variable for LAC to control for regional differences not controlled by GDP levels<sup>14</sup>.

Most of the variability in our sample comes from differences across countries and regions, and from some time series variance within the LAC sample. There is very little time-series variability in the OECD sub-sample. Given this variation, fixed effects (FE) estimates are likely to be very imprecise because they only use the time-series variation within the LAC sample. Instead, random effects (RE) or pooled OLS estimates, that use both the cross-section and the time-series variation included in the sample, are likely to produce estimates with smaller standard errors. Yet, the latter estimates will be biased if variables included as controls are correlated with country specific error terms. To protect against the bias that results from using one estimator, we estimate our basic specification by pooled OLS, RE and FE, comparing whether these different methodologies yield similar point-estimates.

The results, presented in Tables 6.a to 6.c, are striking. First, the point-estimates for the JS coefficient in the total employment specifications are very similar across estimation methodologies. The three estimates suggest a large negative effect of JS on employment rates. This effect is strongly statistically significant in the OLS and the RE estimates while it is not statistically significant, at conventional levels, in the FE case. One obvious advantage of using a cardinal measure of JS is that we can quantify the impact of these provisions on employment. The magnitudes of JS elasticities are quite large: an increase in expected dismissal costs equivalent to one month of pay is associated with a 1.8 percentage points decline in employment rates. Given that in Latin America the average dismissal cost in 2000 was 3.04 months (See Graph 1), the estimated loss in employment –as a percent of total working population-- due to JS provisions is about 5.5 percentage points.

In addition, OLS, FE and RE estimates suggest that JS does not affect the employment rates of all workers in the same fashion. Thus, while the impact on prime-age male employment rates is half the impact on total employment, the impact on young workers' employment rates is almost two times larger. The magnitudes are huge. The OLS and the RE estimates suggest that JS reduces LAC youth employment rates by almost 10 percentage points. This effect is even larger in the FE estimates. Moreover, these magnitudes are consistent with the ones obtained in Pagés and Montenegro (1999) for Chile.

---

<sup>14</sup> These specifications should include a measure of labor costs that include wages and other non-wage labor costs. Unfortunately, a

Our estimates of the effect of JS on female employment rates, self-employment and unemployment rates are less consistent. The point estimates for female employment rates change from negative to positive across methodologies, but in no case are the estimates statistically significant. These results suggest that women are less negatively affected by JS than men but, as we will show, these results are not robust across regional sub-samples.

The estimates of the effect of JS on self-employment also change signs across OLS, FE and RE estimates. Thus, while the pooled estimates suggest a *positive* and statistically significant association between the strength of JS provisions and self-employment (as found by Marquéz (1998)), the FE estimates show a negative and also statistically significant relationship between both variables. It is clear that more empirical work is required to reach a definitive conclusion on the relationship between JS and self-employment.

Finally, the empirical results on unemployment also greatly depend on the methodology used to estimate the parameters. While OLS and RE yield positive (and often statistically significant) coefficients on JS in all the unemployment specifications, FE yields negative and statistically insignificant results. We do not find a significant relationship between the proportion of workers unemployed for more than 6 months and the strictness of JS provisions. Since there is no a priori relationship between disemployment and unemployment, these results are not surprising, especially given differences across regions in the levels of social insurance.

Divergence across estimation methods may result from regional differences in the relationship between JS and some of the variables. This is particularly relevant for our exercise since FE estimates discard practically all of the information for OECD countries. We therefore investigate whether our results are driven by any of the two sub-samples, by estimating separate coefficients for LAC and OECD countries. The results from this exercise are presented in Table 7. While this approach results in small samples and lower statistical significance, the results are still quite remarkable. First, in all the employment specifications, with the exception of female employment rates, the coefficients on job security are negative across regions and estimation methods. In addition, most of the coefficients are highly statistically significant.

---

complete and comparable measure of labor costs across countries and time is not available.

Second, with one exception, all coefficients of the effect of job security on unemployment rates are positive both in OECD and in LAC countries. However, the impact on unemployment rates seems much larger in the industrial country sub-sample, in particular for women and youth. It should not come as a surprise that the effect of JS on unemployment rates is smaller in developing countries. In the absence of unemployment insurance or other income support programs, workers either quickly find other (less attractive jobs) or drop out of the labor force.<sup>15</sup> The positive and statistically coefficient of GDP level in the unemployment regressions reported in Tables 6a-6c confirms this effect.

Third, the ranking of effects between total, male and young workers employment rates is preserved. The point estimates tend to be larger (in absolute value) in the LAC sample. It is very likely that the higher level and variability of JS in this region contributes to these larger (in absolute value) point estimates. It is quite puzzling, however, that the estimates for female employment (and unemployment) rates are so different across regions. Thus, while, JS is negatively associated with female employment rates in the OECD sub-sample, this relationship is actually positive in the LAC sample. The added worker effect is more evident in LAC, where adult female attachment to the labor force is still weak. Understanding gender differences in the impact of JS remains one important issue for further research.

Finally, the evidence of the impact of job security on the formal/informal composition of employment is not conclusive. A comparison of our estimates for LAC with the elasticities obtained from the individual-country studies (see table 3), suggest that the decline in employment associated with JS is greater in the covered (formal) sectors--such as the manufacturing sector or sectors with large-firms--than in the aggregate.<sup>16</sup> This would imply that an increase in job security is associated with a decline in formal employment and an increase—although not enough to compensate the decline in formal jobs—in informal employment. However, the estimates for self-employment—usually considered part of the informal employment--in Table 7 Panel A, indicate an unstable effect of JS on self-employment. While the coefficient resulting from OLS estimation is positive and significant, the coefficient resulting from fixed effect estimation is negative and statistically significant. More research is necessary to understand the relationship between uncovered employment and job security in Latin America.

---

<sup>15</sup> In the case of Chile, Montenegro and Pagés (1999) found that the large effects of JS on youth employment rates were compensated with a large decline in participation rates with no significant effects on unemployment.

<sup>16</sup> The Heckman and Pagés elasticities, reported in Table 3, are obtained from a model identical to the one reported in Table 6, but where job security provisions enter the specification in logs.

## 5. Conclusions

In a recent article, Freeman (2000) writes that “the institutional organization of the labour market has identifiable large effects on distribution, but modest hard-to-uncover effects on efficiency.” This view is shared by many economists (see Abraham and Houseman (1994) and Blank and Freeman (1994)). However, the results summarized in this paper suggest that job security regulations have a substantial impact on employment and turnover rates both in Latin America and in OCED countries and thus substantially affect the efficiency of the labor market.

The assertion that job security does not have any impact on employment rates is based on evidence on unemployment, not on employment. However, employment and unemployment are not mirror images of each other. In addition, while there is substantial evidence that unions reduce earnings inequality in industrial countries, there is no evidence that job security provisions reduce income inequality. Indeed, given that job security reduces the employment prospects (and possibly wages) of younger and less experienced workers, who bear the brunt of regulation, it is likely that regulation widens earnings inequality across age groups. Thus, there is no trade off between employment and inequality associated with job security provisions. Such provisions worsen both. The choice of labor market institutions matters.

What policy lessons can be drawn from these results? Our evidence suggests that job security provisions are an extremely inefficient and inequality-increasing mechanism for providing income security to workers. They are inefficient because they reduce the demand for labor; they are inequality-increasing because some workers benefit while many others are hurt. Their impact on inequality is multifaceted: Job security increases inequality because it reduces the employment prospects of young, female and unskilled workers. It also increases inequality because it segregates the labor market between workers with secure jobs and workers with very few prospects of becoming employed. Finally, job security provisions increase inequality if, as predicted by some theoretical studies and most of the available empirical evidence, they increase the size of the informal sector.

In this light, it seems reasonable to advocate the substitution of job security provisions by other mechanisms that provide income security at lower efficiency and inequality costs. However, reducing dismissal costs is a difficult policy to implement in most countries. The persistence of these policies can be

explained by a demand for income security for groups with political power (Caballero and Hammour, 2000). A demand for income security arises because job security lowers flows out of unemployment and into employment. Although job security reduces the probability of exiting employment, conditional on having lost a job, the probability of finding a new one is reduced. This produces a sense of insecurity among protected workers, who exert pressure to maintain high levels of job security provisions. A balance of power that favors insider workers helps to sustain job security provisions. Thus, those workers most likely to benefit from such provisions are also more likely to be represented in the political process. Instead, outsider workers are less likely to influence policy. Reform minded policymakers should pursue broad coalitions including representatives of outsider workers --such as young, female, unemployed or discouraged workers-- to obtain support for labor market reforms.

## Appendix

### Construction of the index of job security

The job security index is constructed according to the following formula:

$$Index_{jt} = \sum_{i=1}^T \beta^i d^{i-1} (1-d) (b_{jt+i} + aSP_{jt+i}^{jc} + (1-a)SP_{jt+i}^{uc})$$

where  $j$  denotes country,  $d$  is the probability of remaining in a job,  $\beta$  is the discount factor,  $T$  is the maximum tenure that a worker can attain in a firm,  $b_{jt+i}$  is the advance notice to a worker that has been  $i$  years at a firm,  $a$  is the probability that the economic difficulties of the firm are considered a justified cause of dismissal,  $SP_{jt+i}^{jc}$  is the mandated severance pay in such event to a worker that has been  $i$  years at the firm, and finally,  $SP_{jt+i}^{uc}$  denotes the payment to be awarded to a worker with tenure  $i$  in case of unjustified dismissal.<sup>17</sup>

The constructed index measures the expected discounted cost, at the time a worker is hired, of dismissing a worker in the future. The assumption is that firms evaluate future costs based on current labor law. The index only includes statutory provisions, and thus, it does not include provisions negotiated in collective bargaining or included in company policy manuals. In addition, it does not include dismissal costs that are ruled by a judge if a firm is taken to courts. This assumption explains why dismissal costs—according to our index—are zero in the U.S., despite the substantial potential costs associated with legal actions. High values of the index indicate periods or countries of high job security, whereas lower values characterize periods or countries in which dismissal costs are lower. By construction, this index gives equal weight to notice periods and to severance pay since both are added up in the calculation of the dismissal costs. This index however gives a higher weight to dismissal costs that may arise soon after a worker is hired—since they are less discounted at the time of hiring—while it discounts firing costs that may arise further in the future.

In computing the index, we assumed a common discount rate and a common turnover rate of 8% and 12%, respectively. The choice of the discount rate is based on the average return of an internationally diversified portfolio. Finally, the choice of turnover rate is based on the fact that real turnover rates are

unobservable in countries with job security provisions since the turnover rate, is itself affected by job security. We therefore choose to input all countries with the observed turnover rates in the U.S., the country in the sample with the lowest job security. The minimum tenure at a firm is considered to be one year, and the maximum is assumed to be twenty years.

We compute  $SP_j^{jc}$  and  $SP_j^{uc}$  based on the two different sources. For LAC countries, we use the legal information summarized in Table 1.A. This information was directly obtained from the Ministries of Labor of the region. In the case of Colombia we consider that severance payment prior to the 1990 reform was one month and  $\frac{1}{2}$  per year of work instead of one--as prescribed by law--to include that prior to the 1990 reform, advance withdrawals to the seniority premium fund were accounted in nominal terms. High inflation rates implied that this practice substantially increased overall dismissal costs. For OECD countries, we use the legal information summarized in OECD (1999). In all Latin American countries but Argentina and Chile, economic conditions are not a just cause for dismissal. Consequently, we assumed  $a=0$  for those countries. Instead, in Argentina, Chile, economic conditions were a justified cause of dismissal and therefore,  $a=1$ . For OECD countries, we used the information summarized in Table 2.A.2 OECD (1999) to parameterize severance payments and advance notice. In all cases, but in Spain,  $a=1$ . In Spain, mandatory severance pay in the case of unjustified cause was substantially larger than severance pay for just cause. Consequently most workers fired for just cause appealed to the courts, and there was a high probability that a judge would declare a dismissal unjustified. Based on Bertola, Boeri and Cazes (2000), we assume that prior to the 1997 reform,  $a=0.2$ . After 1997, the scope for ambiguity was reduced and  $a=0.5$ . For Canada, we used the information relevant to the federal jurisdiction (although JS provisions may vary across states). Finally, in some European countries statutory dismissal costs vary across blue and white-collar workers. To obtain a single measure per country, we compute a separated index for blue and white-collar workers and performed a simple average among the two. (See OECD, 1999 for a description of dismissal costs in OECD countries and the cost divergences between blue-and white-collar workers.)

### Definition of Variables used in Empirical Section

**Total Employment.** All employed workers between 16 and 65 that declared having a job in the week of reference. It is measured as % of total population 16-65. All measures of aggregate employment include formal and informal workers. They also include unpaid workers. Source: OECD statistics and LAC household Surveys.

**Prime Age-Male Employment:** % of men 25-50 years old employed in the week of reference. Source: OECD statistics and LAC household Surveys.

**Prime Age-Female Employment:** % of female 25-50 years old employed in the week of reference. Source: OECD statistics and LAC household Surveys.

**Youth Employment:** % of people 16-24 years old employed in the week of reference. Source: OECD statistics and LAC household Surveys.

**Self-Employment:** Share of non-agricultural workers in self-employment or as owners of firms. Source: Maloney (1999)

**Total Unemployment:** # of people 16-65 that did not work in the week of reference but are actively looking for a job as a % of total active population in that age group. Source: OECD statistics and LAC household Surveys.

**Prime-Age Male Unemployment:** # of men 25-50 that did not work in the week of reference but are actively looking for a job as a % of male active population in that age group. Source: OECD statistics and LAC household Surveys.

**Prime-Age Female Unemployment:** # of people 25-50 that did not work in the week of reference but are actively looking for a job as a % of female active population in that age group. Source: OECD statistics and LAC household Surveys.

**Youth Unemployment:** # of people 16-24 that did not work in the week of reference but are actively looking for a job as a % of active population in that age group. Source: OECD statistics and LAC household Surveys.

**Long-term unemployment:** # of people 16-65 that have been without a job, and actively looking for one for more than 6 months as a % of total active population in that age group. Source: OECD statistics and LAC household Surveys.

**Female Participation:** % of total female workers 16-65 that are either employed or actively seeking one. Source: OECD statistics and LAC household Surveys.

**GDP:** Gross Domestic Product measured in 1995 US dollars. Source: World Bank.

**Population 15-24:** Proportion of population in this age group. Source: UN Population Statistics

The Effect of Job Security Regulations on Labor Market Flexibility:  
Evidence from the Colombian Labor Market Reform

Adriana D. Kugler

NBER Working Paper No. 10215

January 2004

JEL No. J41, J63, J64, J65, J68

### **ABSTRACT**

Job security provisions are widely believed to reduce dismissals and hiring. In addition, in developing countries job security is believed to reduce compliance with labor regulations and to increase informal activity. Reductions in dismissal costs are, thus, often advocated as a way to increase labor market flexibility and to increase compliance with labor regulations. This paper analyzes the impact of a substantial reduction in dismissal costs introduced by the Colombian Labor Market Reform of 1990. A theoretical model illustrates the effect of dismissal costs when there is a noncompliant sector. The model shows the direct effect of a reduction in dismissal costs on increased turnover as well as the second order effects on wages and on the composition of the compliant and noncompliant sectors. Using microdata from the Colombian National Household Surveys, I exploit the temporal variability in dismissal costs together with the variability in coverage between formal and informal workers (who are not covered and were, thus, not directly affected by the reform). The differences-in-differences results indicate increased separations and accessions for formal workers relative to informal workers after the reform. Moreover, the increase in worker turnover was greatest among younger workers, more educated workers, and workers employed in larger firms who are most likely to have been affected by the reform. The estimates, together with the steady-state conditions of the model, suggest the reform contributed to 10% of the reduction in unemployment during the period of study.

## **I. Introduction**

Job security regulations are usually considered to inhibit labor market flexibility by reducing the ability of firms to hire and fire workers. While severance pay and other job security provisions admittedly protect workers from unjust termination, these laws may also adversely affect workers by reducing their ability to find new jobs. State-mandated severance pay and job security requirements are equivalent to taxes on job destruction that reduce firms' incentives not only to dismiss but also to hire new workers. In fact, it has often been suggested that the elevated severance pay and job security requirements in Europe are in part to blame for the high unemployment levels in this continent.

The perception that reducing firing costs would help to reduce unemployment by enhancing labor market flexibility, through increased worker turnover into and out of unemployment, has driven several European countries to introduce labor market reforms in this direction. In particular, a number of countries including, England, France, Germany, and Spain, introduced temporary contracts during the 1980's as a way of reducing severance payments and payments for unjust dismissals. In contrast, American labor markets became more rigid during the 1980's. During this decade, a number of states in the U.S. introduced indemnities for unjust dismissals, thus, creating exceptions to the employment-at-will doctrine.

Although the evidence on the effects of these legislative changes on employment and unemployment in Europe and the U.S. has been ambiguous, reforms to reduce labor market rigidities have also been advocated and implemented in a number of less developed countries. In less developed countries the effects of these reforms are considered to be even greater, as labor market regulations are considered not only to discourage hiring and firing, but in addition to encourage noncompliance with labor legislation and the expansion of the informal sector.

In this paper, I consider the incidence of a substantial reduction of firing costs on flexibility and unemployment in a less developed country. In particular, this paper studies the impact of the Colombian labor market reform of 1990, which reduced severance payments substantially, on worker flows into and out of unemployment and its implied net effect on unemployment. I use a micro-level data set from Colombia to examine the effects of a reduction in firing costs on worker turnover. The labor market reform introduced in Colombia in 1990 reduced severance payments for all workers hired after 1990 and covered by the legislation (formal sector workers). Informal workers, who are not covered by the legislation, were not *directly* affected by the reform and, thus, are used as a comparison group in the estimations. The empirical analysis exploits this variability in the coverage of the legislation between formal and informal sector workers together with the temporal change in the Colombian legislation to identify the effects of a reduction in firing costs on the exit rates out of employment and out of unemployment. The Colombian Household Surveys for June provide information about formal and informal sector activity and allow estimating hazard rates for formal and informal workers, before and after the reform. The results of the hazard models using a differences-in-differences estimator indicate that hazard rates into and out of unemployment increased after the reform for formal sector workers (covered by the legislation) relative to informal workers (uncovered). Moreover, the increase in worker turnover was greater among younger more educated workers employed in larger firms who are likely to have been affected most by the changes in the legislation.

The rest of the paper proceeds as follows. In Section II, I survey the evidence on the effect of firing costs on employment volatility, the speed of employment adjustment, and employment levels, labor market participation, and unemployment for developed countries. In

Section III, I describe the legislative changes, introduced by the Colombian labor market reform of 1990 that led to a reduction in severance pay and other firing costs. In section IV, I develop a matching model with endogenous sorting into a formal and an informal sector. The model is useful as it predicts the direct effect of a reduction in severance pay on worker turnover as well as the general equilibrium effects of the reform on turnover in the two sectors. Section V discusses the identification strategy of the firing cost effects on worker turnover. In Section VI, I describe the data and present the results on the incidence of firing costs on the exit rates into and out of unemployment. In Section VII, I use the steady-state condition from the model together with the results in Section VI to estimate the net impact of the reform on unemployment. Section VIII concludes.

## **II. Review of the Literature**

The perception that flexible labor markets promote employment and reduce unemployment is widely accepted. Yet, the theoretical and empirical evidence on the net effects of firing costs on employment and unemployment are ambiguous.

Past theoretical work on the effects of firing costs shows that while reductions (increases) in firing costs are expected to increase (reduce) hiring and firing as well as employment volatility, the net effects of reductions in firing costs on employment and unemployment are ambiguous. Theoretically, the net effect of firing costs on employment is very sensitive to the assumptions of the model. The net effect of firing costs on employment depends crucially on whether the entry-exit margin is considered and on the stochastic process assumed to be generating the demand shocks. Hopenhayn and Rogerson (1993) simulate the effect of firing costs in a general equilibrium framework with firm entry and exit and they find that an increase in firing costs reduces employment. On the contrary, Bentolila and Bertola (1990) consider a

partial equilibrium model with a monopolistic firm and find that employment increases slightly with firing costs, because the firing effect dominates the hiring effect. In addition, Bentolila and Dolado (1994) argue that in an insider-outsider model a-lá Lindbeck and Snower (1988), firing costs may strengthen the position of insiders and increase their employment while reducing the employment of outsiders.

Similarly, past empirical evidence indicates that lower firing costs are related to greater employment volatility, but the evidence of the net effect of firing costs on employment and unemployment in these studies has been mixed. Bertola (1990) constructs job security indices for ten countries and finds that job security provisions are negatively correlated with the variance of employment and with unemployment's response to output changes (i.e., Okun's coefficient). Using a panel of retail firms in the U.S., Anderson (1993) finds that the seasonal variability in employment is lower in firms facing higher adjustment costs. Moreover, a number of studies have related the speed of employment adjustment to shocks to the level of firing costs. As predicted by the theory, Anderson (1993) finds that the probability of responding to shocks is negatively correlated to the adjustment costs faced by firms. In addition, Hamermesh (1993) finds that the speed of employment adjustment to shocks fell in non-unionized industries over the 1980's in the U.S., when exceptions to the employment-at-will doctrine were being introduced. Using British data Burgess (1993) finds a lower speed of employment in industries subject to higher firing costs. Bentolila and Saint-Paul (1992) also find that employment adjustments over the business cycle increased in Spain after the introduction of temporary contracts in 1984. Thus, these studies provide evidence of the greater employment volatility when firing costs are lower.

The evidence on the impact of firing costs on employment and unemployment, however,

appear mixed. Lazear (1990) uses cross-country data from 22 developed countries over 29 years and finds evidence suggesting that high severance payments and advance notice requirements reduce employment and labor force participation. Grubb and Wells (1993) construct job security indices for OECD countries and also find a negative correlation between job security and employment. Di Tella and MacCulloch (2004) use a measure of flexibility provided by employers and they find that flexibility is positively correlated with employment and participation, and to a lesser degree with unemployment. In contrast, Bertola (1990) finds evidence suggesting that job security provisions are unrelated to medium and long run employment. Nickell and Layard (1999) find that employment and labor force levels are lower when employment protection legislation (EPL) is stricter, but since they are exploiting cross-country variation they cannot control for the fact that female labor force participation is lower and EPL stricter in Southern European countries. In fact, they find that the results disappear when considering a sample of adult males. The OECD's Employment Outlook (1999) exploits additional temporal variation in EPL and finds no effect of EPL on aggregate employment. However, consistent with the story that EPL protects insiders, the Employment Outlook finds that EPL increases the employment of adult men and reduces the employment of young workers and women.

Exploiting the temporal change in the labor legislation across states in the U.S., Dertouzos and Karoly (1993) find employment levels fell in states that introduced more stringent employment protection. In contrast, Miles (2000) finds no effect of the changes in unjust dismissal costs in the U.S. on aggregate employment. However, both Autor (2003) and Miles (2000) find that stricter employment protection contributed to the rise in temporary employment in the U.S. over the 1980's. Anderson (1993), instead, exploits the experience-rating feature of

the U.S. unemployment insurance system to quantify adjustment costs and finds higher average employment in firms subject to higher adjustment costs. The mixed results observed in the literature are not surprising if one considers that cross-section studies are subject to omitted variable biases, simultaneity problems, and endogeneity of the legislation. The panel studies while mitigating the concerns of omitted variable biases and simultaneity are subject to the possibility of endogeneity of the legislation as well as to selection biases. Thus, while the evidence on the effects of firing costs on the volatility of employment appears robust, the net effect of firing costs on employment and unemployment is not as clear.<sup>1</sup>

More recently, a handful of studies have exploited the differential variation in labor legislation for certain groups of workers to set up natural experiments of the impact of firing costs using microdata. While Acemoglu and Angrist (2001) find no effect of the American with Disabilities Act on separations of disabled relative non-disabled, Oyer and Schaefer (2000) find substitution of individual dismissals for mass layoffs after the passage of the Civil Rights Act of 1990 for groups covered by the legislation. Kugler and Saint-Paul (2003) and Autor, Donohue and Schwab (2003) find increased hires and employment in those states that introduced certain unjust dismissal provisions over the 1980's. Finally, Kugler, Jimeno and Hernanz (2003) find increased hiring of young workers and increased separations of older workers after the introduction of the Spanish labor market reform of 1997, which reduced dismissal costs and payroll taxes for these groups of workers.

While micro studies solve some of the problems in studies relying on macrodata, these studies have focused on the impact of firing costs in developed countries. There is little

---

<sup>1</sup> However, a number of recent studies, including Angrist and Kugler (2003), Bertola, Blau and Kahn (2003), and Blanchard and Wolfers (2000), find that the negative effects of labor market institutions on employment and unemployment are realized when economies are faced with bad shocks.

evidence on the impact of firing costs in less developed countries. In the next section, I describe the legislative change introduced in Colombia in 1990, which allows to exploit the temporal variability and the variability in coverage of labor legislation to estimate the impact of firing costs on turnover and unemployment in a less developed country.

### **III. Changes in the Colombian Institutional Framework**

In 1990, Colombia introduced a labor market reform that substantially reduced the costs of dismissing workers. The Colombian reform reduced severance payments, widened the definition of ‘just’ dismissals, extended the use of temporary contracts, and speeded up the process of mass dismissals. All of these policy changes reduced the costs of firing workers covered by the legislation after 1990.<sup>2</sup> The reform, thus, reduced firing costs for firms in the formal sector but not for informal firms, which did not comply with labor legislation.

Although the reform introduced various legislative changes simultaneously, the one major policy change that decreased the costs of dismissals was the reduction of severance payments.<sup>3</sup> The reform reduced the severance paid for dismissals in three ways. First, prior to the reform, employers were mandated to pay severance of one month per year worked based on the salary at the time of separation. After the reform, employers were, instead, required to deposit a monthly contribution equivalent to one month of the yearly salary at that moment in time to an individual severance payments savings account (“Fondo de Cesantías”), which would be accessible to workers in the event of separation. Thus, total severance payments were reduced because the monthly payment per year worked was no longer based on the higher salary at the

---

<sup>2</sup> In addition to the Labor Market Reform of 1990, a social security reform was passed in 1994 and implemented in 1995 and 1996. However, since the social security reform increased payroll taxes, the increase in non-wage recurrent costs of this reform implies different effects on turnover than the reduction in dismissal costs of the Labor Market Reform of 1990. Moreover, the study by Gruber (1997) of a similar reform in Chile finds no effects of payroll taxes on employment because recurrent costs are passed onto wages.

<sup>3</sup> Note that both before and after the reform, employers were exempt from the payment of severance in cases when employees were dismissed because of undue care, sabotage, or release of employers’ proprietary information.

time of separation, but rather on the salary during each month. Second, prior to the reform, workers could obtain advance payments from their severance to use for investments in education and housing, that would only be credited to the employer in nominal terms in the event of separation. After the reform, although the withdrawal of funds was still permitted, these ‘loans’ were now credited to the employer in real terms. According to Ocampo (1987), the fact that, prior to the reform, withdrawals were credited to the employer in *nominal* terms implied, on average, a cost of 35% of the total severance payments in the manufacturing sector prior to 1990. Finally, the change in the legislation reduced severance pay, because the introduction of guaranteed severance payments essentially turned severance payments into a deferred compensation scheme, allowing workers lower wages in exchange for future severance.<sup>4</sup> Not all workers were, however, affected in the same way by the reduction in severance payments. As indicated above, workers hired by informal firms are not covered by the legislation and, thus, should not had been affected directly by the reform. Moreover, family workers, temporary workers, and workers employed by firms with 5 or less employees are not entitled to severance payments, and domestic workers and workers employed by firms with very little capital are entitled only to a severance payment of 15 days per year worked.

A second important change introduced by the reform was the change in the legislation with regards to indemnities for ‘unjust’ dismissals. First, the definition of ‘unjust’ dismissals changed in 1990. Prior to the reform, ‘just’ cause dismissals included dismissals of employees because of fraud, violence, undue care, sabotage, discipline problems, deficient performance, and release of proprietary information. After the reform, the definition of ‘just’ cause dismissals was extended to include any dismissal for failure to comply with firm regulations and instructions

---

<sup>4</sup> Kugler (2002) studies the impact a change from a standard severance payments system into a system of severance payments savings accounts.

from one's supervisors. The exemptions for the payment of indemnities for 'unjust' dismissals were thus extended after the 1990 reform, reducing firing costs for formal firms. Second, the reform eliminated the ability of workers with more than ten years of tenure to sue for backpay and reinstatement. At the same time, however, the reform increased the cost of 'unjustly' dismissing workers with more than ten years of tenure (see Table 1) and this may have increased the incentives for firms to dismiss workers just before reaching 10 years of seniority.<sup>5</sup> Thus, these changes in 'unjust' dismissal legislation can be expected to have the greatest impact on formal workers with intermediate levels of seniority.

Another important change brought about by the reform was the extension of the use of fixed-term contracts.<sup>6</sup> Prior to 1990, fixed term-contracts were allowed for a minimum duration of a year.<sup>7</sup> After the reform, these fixed-term contracts were extended to contracts of less than a year (renewable up to three times). This change in the legislation, thus, lowered firing costs for firms hiring workers for less than a year and would be expected to have increased turnover among formal workers with less than a year of tenure after the reform.

An additional change introduced by the reform was a reduction in the advance notice for mass dismissals. While advance notice requirements for mass layoffs existed prior to the reform (see Table 2), the reform introduced penalties to bureaucrats who did not process requests for mass layoffs quickly. If such threats to bureaucrats were effective, this change in the legislation should have speeded up the dismissal process for formal firms and lowered their costs of firing.

Finally, the reform also introduced a new type of contract that eliminated severance

---

<sup>5</sup> Note, however, that employees with more than ten years of experience hired before 1990 could also choose to be covered by the new regime with Severance Payments Savings Accounts.

<sup>6</sup> While temporary contracts are subject to payroll taxes and social security contributions, these contracts are not subject to severance pay and 'unjust' dismissal legislation as long as contracts end by the agreed date.

<sup>7</sup> Despite legislation on fixed-term contracts, however, firms could circumvent this restriction by subcontracting workers from temp agencies even prior to the reform.

payments altogether. This type of contract (“Salario Integral”) allowed formal workers who earned more than ten times the minimum wage to opt out of severance payments, indemnities for unjust dismissals, benefits (except paid vacations), social security contributions, and payroll taxes in exchange for a higher salary. The introduction of this type of contract effectively allowed firms to eliminate the cost of dismissing highly paid workers who opted for the “Salario Integral”. Thus, one would expect to find a greater effect of the reform on formal sector workers with salaries above ten minimum wages.<sup>8</sup>

The changes in severance pay legislation, ‘unjust’ dismissal legislation, temporary contracts, and mandatory advance notice introduced by the Colombian Labor Market Reform should have directly reduced the costs of dismissals for formal firms and increased turnover in the formal sector. Moreover, it is often argued that job security regulations simply encourage the expansion of the informal sector and one would, thus, expect for this type of reform to have encouraged greater compliance with the legislation. The next section introduces a matching model with firing costs, which shows the direct effect on formal turnover of a reduction in firing costs as well as the indirect effects on formal and informal turnover through the compositional changes of firms in each sector. The model shows that a reform that reduces dismissal costs may not only increase turnover, but it may also increase compliance with state-mandated firing costs.

#### **IV. A Sorting Model of Compliance with Job Security Provisions**

This section presents a matching model with a formal sector and an informal sector in which firms sort themselves between the two sectors. Firms producing in the formal sector must comply with labor legislation and have to pay state-mandated severance in the event of a

---

<sup>8</sup> By 1994 only 1.5% of all workers in manufacturing and 0.6% of workers in commerce had opted for this type of contract (Lora and Henao, 1995). Since the surveys used in the analysis do not indicate whether a worker indeed opted for an Integral Salary, we examine whether the impact of the reform was greater on older and highly educated workers who are more likely to earn above ten minimum wages.

dismissal, while firms in the informal sector do not comply with job security legislation and avoid the severance payment. Productivity in the informal sector is, however, lower overall than in the formal sector because informal firms must produce at a smaller scale to remain inconspicuous to the authorities. Moreover, the presence of a firm-specific component to productivity in the model implies that, in equilibrium, firms with higher idiosyncratic productivity self-sort into the formal sector while firms with lower idiosyncratic productivity self-sort into the informal sector.

The model predicts that the probability of being dismissed by a formal firm is lower because of the legislated severance payments, but also because formal firms are more productive. Also, a reduction in severance payments increases the probability of dismissals in the formal sector through a direct effect on the firing costs. In addition, however, the reduction in firing costs has effects on the idiosyncratic composition of firms in each sector as well as on the wages paid in each sector. This model, thus, highlights the potential biases that may arise in empirical studies that attempt to quantify the effects of firing costs.

### **A. Assumptions**

In this model, heterogeneous firms may choose to produce in a formal sector in which they must comply with job security provisions or to produce in the informal sector without complying but at the cost of lower productivity. Workers are identical *ex-ante*, but they may have different productivity *ex-post* depending on how well they match. After a match, the firm and worker set the wage according to a Nash-bargaining solution. Then, the firm decides whether to keep or dismiss the worker.

### **Production in Each Sector**

Formal and informal production is a function of a sector-specific component,  $a_s$ , of a

firm-idiosyncratic component,  $A$ , and of the match-quality component,  $\gamma$ , and produce with a technology,  $Y_s = a_s \gamma A$ , for  $s = F, I$ . Sector-specific productivity is fixed and it is assumed, without loss of generality, that  $a_F = 1 > a_I = a$ . The firm-idiosyncratic component comes from a distribution  $F(A)$ , and the match-quality component comes from a distribution  $G(\gamma)$ .

### **Timing**

Firms, first, observe their firm-specific productivity. Firms then choose a sector given the productivity in the sector and their known firm-specific productivity. Formal and informal firms hire in the same market and, immediately after hiring, they observe the match-specific productivity. Then, firms and workers bargain over wages. At the end of the process firms decide whether to keep or dismiss the worker, and formal firms that do dismiss must provide a severance payment,  $C$ . However, workers may still be separated afterwards at arrival rates,  $\lambda_F$  and  $\lambda_I$ , due to exogenous reasons, in which case firms do not pay severance.

### **Matching**

All firms and workers search in the same market. The arrival rate of applicants to formal and informal firms is the same,  $q(\theta) = m(1/\theta, 1)$ , where  $\theta = v/u$ . The arrival rate of job opportunities is  $\theta q(\theta)$ , and workers receive offers from formal or informal firms with a given probability that depends on the share of firms in each sector.

### **Wage-setting**

Each firm and worker pair sets the wage based on Nash bargaining. Wages are set after firm-specific and match-specific productivities are observed. In this model, all wages are affected by job security legislation, because the severance pay raises the utility of the

unemployed and thus raises the reservation wage of all workers.<sup>9</sup>

## B. Solution to the Model

The model is solved by backward induction. First, the solution for the dismissal choices in each sector is found. Second, the Nash-bargaining solution of the wage is determined. Finally, the marginal firm between the two sectors is determined to solve for the split of firms between the formal and informal sectors.

### Dismissal Decisions

The present discounted profits for a firm with a filled job is  $J_s$  and the present discounted value of a vacant job is  $V_s$ , for  $s = F, I$  (formal and informal, respectively). Thus, the asset equation of a filled and a vacant job are given by the following equations, respectively:

$$r J_s = Y_s - w_s + \lambda_s (V_s - J_s),$$

$$r V_s = q(\theta) (J_s - V_s),$$

As there is free-entry, and all profit-opportunities are exploited,  $V_s = 0$ . Thus,

$$J_s = [a_s \gamma A - w_s] / (r + \lambda_s + q(\theta)).$$

Once matched, a firm must choose whether to keep or dismiss a worker. A formal firm has to pay a cost,  $C$ , if it decides to dismiss, while an informal firm does not have to pay the firing cost.

Thus, the minimum match-productivity that triggers a dismissal by a formal firm is given by,

$$\bar{\gamma}_F = [w_F - C (r + \lambda_F + q(\theta))] / A.$$

For informal firms, the trigger productivity is given by,

$$\bar{\gamma}_I = [w_I] / aA.$$

---

<sup>9</sup> As pointed out by Lazear (1990), in a perfectly competitive market, the state-mandated severance pay could be undone given the proper contract. In particular, the worker would have to post a bond for the cost of the severance pay to the firm upon the signing of the contract. However, as in Lazear (1990), it is assumed that the state-mandated severance pay is not completely offset by a private transfer, because workers may be liquidity constrained and because of moral hazard problems on the part of firms.

Given firm-specific productivity and wages, the probability that a formal firm dismisses a worker is less than the probability that an informal firm dismisses, i.e.,  $\bar{\gamma}_F < \bar{\gamma}_I \Leftrightarrow G(\bar{\gamma}_F) < G(\bar{\gamma}_I)$ . This is both because formal firms must pay severance payments and because sector productivity is higher if producing formally.

### Determination of Wages

Wages are set by each firm-worker pair before the match-quality is realized. Wages are set according to Nash-bargaining, where each side has the same bargaining power. Thus, formal and informal firms split their surplus equally with workers, as follows:

$$J_F^e - V_F - G(\bar{\gamma}_F)C = E_F^e - U,$$

$$J_I^e - V_I = E_I^e - U,$$

where  $J_F^e$ ,  $J_I^e$ ,  $E_F^e$ , and  $E_I^e$  are the expected discounted profits of a formal and informal job and the expected lifetime utilities of a formal and an informal worker, respectively, and  $U$  is the expected lifetime utility of an unemployed worker. The asset equations of employed and unemployed workers are given by,

$$r E_s^e = w_s + \lambda (U - E_s^e),$$

$$r U = \theta q(\theta) (E^e - U).$$

Where  $E^e$  is the expected lifetime utility of employment for an unemployed job-seeker. Since an unemployed worker is uncertain about whether he will be hired in a formal or an informal job, his expected utility of employment is:

$$E^e = \text{Pr}(\text{formal offer}) [ (1 - G(\bar{\gamma}_F)) E_F^e + G(\bar{\gamma}_F) C ] + \text{Pr}(\text{informal offer}) (1 - G(\bar{\gamma}_I)) E_I^e.$$

Solving for  $(E_s^e - U)$  in each sector and substituting into the equal split equation above determines the wages in each sector:

$$w_F = \frac{\{ (r + \lambda_F)(r + \theta q(\theta)) [\int \gamma A g(\gamma) d\gamma - G(\bar{\gamma}_F) C] + r(r + \lambda_F + q(\theta)) \theta q(\theta) E^e \}}{\{ (2(r + \lambda_F) + q(\theta))(r + \theta q(\theta)) \}},$$

$$w_I = \frac{\{ (r + \lambda_I)(r + \theta q(\theta)) [\int \gamma A g(\gamma) d\gamma + r(r + \lambda_I + q(\theta)) \theta q(\theta) E^e \}}{\{ (2(r + \lambda_I) + q(\theta))(r + \theta q(\theta)) \}}.$$

Wages are expected to be higher in the formal sector because of the higher sector-productivity in formal jobs. However, as shown above, in equilibrium the average match-quality is lower in formal sector firms, as firms in this sector are more likely to keep less productive matches than informal firms. Hence, the lower quality of the matches in the formal sector lowers the expected wage in the formal sector. In addition, wages are affected not only by average productivity but also by the level of the firing cost. Both formal and informal wages are raised by the presence of state-mandated severance pay, because the severance payment raises workers' reservation wages.

### Sorting into Sectors

Given dismissal choices and wages, firms choose whether to sort into the formal or the informal sector. The benefit of producing formally is that the productivity of this sector is higher, but the cost of producing in this sector relative to the informal sector is the payment of state-mandated severance in the event of a dismissal. As firms are heterogeneous, firms may split between the two sectors. Firms produce formally if the difference between the expected stream of profits of formal and informal firms is positive, i.e., if  $[J_F^e - J_I^e] > 0$ , and they produce informally if it is negative, i.e., if  $[J_F^e - J_I^e] < 0$ . As the firm-specific productivity increases, the output gains in the formal sector relative to the informal sector increase. Thus, the gains from

going into the formal sector are greater for more productive firms than for less productive ones:

$$d[ J_F^e - J_I^e ] / dA = \int_{\gamma \in [\bar{\gamma}_F, \bar{\gamma}_I]} [ \gamma / (r + \lambda_F + q(\theta)) ] g(\gamma) d\gamma + \int_{\gamma \in [\bar{\gamma}_I, \bar{\gamma}_F]} [ a\gamma / (r + \lambda_I + q(\theta)) ] g(\gamma) d\gamma > 0.$$

Firms with  $A \in [\underline{A}, A_{\text{crit}}]$  produce in the informal sector, while firms with  $A \in [A_{\text{crit}}, \bar{A}]$  produce in the formal sector, where  $A_{\text{crit}}$  is the firm-specific productivity of the firm that is marginal between producing formally and producing informally. Consequently, since formal firms are more productive in equilibrium, they dismiss less often and they pay higher wages than informal firms.<sup>10</sup>

### C. Severance Pay and Turnover

The presence of state-mandated costs and higher productivity in the formal sector imply different hazards into and out of unemployment in the two sectors. On the one hand, the probability of endogenous dismissal in the formal sector is likely to be lower than the probability of dismissal in the informal sector, i.e.,  $\theta q(\theta)(1 - F(A_m))G(\bar{\gamma}_F) < \theta q(\theta)F(A_m)G(\bar{\gamma}_I)$ . On the other hand, the hiring probability will be higher or lower in the formal sector relative to the informal sector depending on the share of firms producing in each sector, i.e., depending on whether  $\theta q(\theta)(1 - F(A_m)) > \theta q(\theta)F(A_m)$  or  $\theta q(\theta)(1 - F(A_m)) < \theta q(\theta)F(A_m)$ . As the proportion of firms producing formally increases, then the hiring probability in the formal sector increases relative to the informal sector.

Moreover, the hazards into and out of unemployment are affected directly and indirectly by changes in severance pay legislation. First, a reduction in state-mandated severance pay has a direct effect on formal firms by increasing the threshold match-productivity that triggers dismissals. Second, a reduction of severance payments pushes down wages in both sectors due

---

<sup>10</sup> The self-sorting of more productive firms into the formal sector, thus, makes evident the problems of identifying the effect of legislation on turnover, simply by estimating the effect of firing cost on the hazard rates.

to the fall in the reservation wage. Wages increase, however, due to the greater probability of dismissal in the formal sector, and the net effect on wages in both sectors is positive as well as the effect of wages on turnover. Finally, a reduction of severance payments changes the composition of firms in each sector. In particular, decreasing severance payments increases the incentives to produce in the formal sector and shifts lower productivity firms, that before were unwilling to produce formally, away from the informal sector. The compositional change increases the dismissal and hiring rates in the formal sector due to the greater share of firms producing formally.

The direct and indirect effects of a reduction in firing costs on turnover that emerge in the model illustrate the problems that may arise when trying to estimate the impact of a change in firing costs on turnover. First, the effects of firing costs on wages imply that the effect of firing costs on turnover captures not only the direct effect mentioned above, but also the indirect effect of firing costs on turnover going through wages. This is not problematic in so far as one is interested in measuring the total effect, both direct and indirect, of firing costs on turnover. However, the self-sorting of firms into formal and informal sectors according to their firm-specific productivity and the effect of the reduction of firing costs on this self-sorting are likely to introduce selection biases. Finally, if a policy change occurred simultaneously with a change in the distribution of the shocks, then one may attribute to the reform an effect that may indeed be due to a worsening in the distribution of the matches.<sup>11</sup> The next section discusses an identification strategy to deal with the problem of contemporaneous changes in the distribution of the shocks and discusses inference given the presence of a selection problem.

---

<sup>11</sup> In addition, a change in firing costs is also likely to affect turnover in both sectors through its indirect effect on wages.

## V. Identification Strategy

### A. Differences-in-differences

The theory laid out above suggests that firing costs should only have direct effects on the exit rates of workers in the formal sector (covered by the legislation), but not on the exit rates of workers in the informal sector (uncovered by the legislation). Hence, the firing costs should only have direct effects on the tenures of formal sector workers, but not on the tenures of workers employed in the informal sector. Similarly, the unemployment duration of workers whose spells end as a result of being hired in the formal sector should be directly affected by firing costs, but not those of workers whose spells end as a result of being hired in the informal sector. Comparing the hazards into and out of unemployment (or tenures and unemployment spells) between formal and informal workers (covered and uncovered by the legislation) could then provide an estimate of the effect of firing costs on turnover. The sample counterpart of the firing cost effect on tenure (unemployment spells) using differences would be:

$$\Delta \bar{s} = [ \bar{s}^{\text{formal}} - \bar{s}^{\text{informal}} ],$$

where,  $\bar{h}^{\text{formal}} = 1 / \bar{s}^{\text{formal}}$  and  $\bar{h}^{\text{informal}} = 1 / \bar{s}^{\text{informal}}$  and the  $\bar{s}$ 's are mean tenures (unemployment spells) and the  $\bar{h}$ 's are mean hazard rates.<sup>12</sup> Considering the simplest possible model of tenure (unemployment duration) with no regressors, tenure (unemployment) depends only on a formal dummy,

$$s_{it} = \beta + \delta \text{Formal}_{it} + u_{it}, \quad E(u_{it} | \text{Formal}_{it})=0.$$

Given this model, it is easy to see that the difference of the mean tenures in the formal and informal sectors provides an estimate of the firing cost effect,  $\delta$ . This way of estimating the firing cost effect is, however, likely to be biased for three reasons. First, the two groups may

have different characteristics and, thus, different turnover behavior and different mean tenures and unemployment spells. Including regressors in the model above allows controlling for observable characteristics and helps to solve this problem. Second, the error term could be correlated with the Formal dummy if there is self-selection into the groups, i.e.,  $E(u_{it} | \text{Formal}_i=1) \neq E(u_{it} | \text{Formal}_i=0)$ . Finally, the two groups may be subject to different shocks and part of the differences in turnover patterns and, thus, tenures and unemployment spells, between the groups may be simply capturing these differences, i.e.,  $\beta_F \neq \beta_I$ .

Exploiting the temporal change in the legislation introduced by the labor market reform of 1990, in addition to the variability in coverage between covered and uncovered workers, allows controlling for self-selection and for the difference in shocks across groups. In the model of tenure (unemployment spells) with no regressors, tenure (unemployment) depends only on a formal dummy, on a post-reform dummy, and on an interaction term between the two,

$$s_{it} = \beta + \delta_0 \text{Formal}_{it} + \delta_1 \text{Post90}_{it} + \delta_2 \text{Formal}_{it} \times \text{Post90}_{it} + u_{it}$$

First, if self-selection is constant over time, i.e.,  $E(u_{i\text{pre}90} | \text{Formal}_i=1) = E(u_{i\text{post}90} | \text{Formal}_i=1)$  and  $E(u_{i\text{pre}90} | \text{Formal}_i=0) = E(u_{i\text{post}90} | \text{Formal}_i=0)$ , the firing cost effect can be estimated by simply taking differences-in-differences:

$$\Delta \bar{s}^{\text{gt}} = \Delta [ \bar{s}^{\text{post}90} - \bar{s}^{\text{pre}90} ]^{\text{formal}} - \Delta [ \bar{s}^{\text{post}90} - \bar{s}^{\text{pre}90} ]^{\text{informal}},$$

where,  $\bar{h}^{\text{gt}} = 1 / \bar{s}^{\text{gt}}$ . Taking differences of average tenures (unemployment duration) for formal workers between the pre-1990 and the post-1990 periods provides an estimate of the firing cost effect and allows to difference out the biases introduced by self-selection when self-selection is constant over time. Taking differences of these differences with respect to informal workers

---

<sup>12</sup> This sample counterpart holds as long as the hazards follow a Poisson process.

(uncovered by the legislation) allows controlling for common trends that affect both groups, whether it is a constant trend,  $\beta$ , or a changing trend common to both groups,  $\delta_1$ .

As indicated above, however, it is possible that the two groups are subject to different shocks, i.e.,  $\beta_F \neq \beta_I$ . In this case, differences-in-differences would work provided that the post-reform shocks can be adjusted using pre-reform trends. Thus, differences-in-differences would work even if the trends were different in the two groups under two circumstances. First, differences-in-differences would work if the trends are constant over time for each group, i.e.,  $\beta_{Fpre90} = \beta_{Fpost90}$ ,  $\beta_{Ipre90} = \beta_{Ipost90}$ , and  $\delta_1 = 0$ . Second, differences-in-differences would also work if the trends change over time for each group, but the trends change by a common factor in both groups, i.e.,  $\beta_{Fpre90} \neq \beta_{Fpost90} = \beta_{Fpre90} + \delta_1$  and  $\beta_{Ipre90} \neq \beta_{Ipost90} = \beta_{Ipre90} + \delta_1$ .<sup>13</sup>

To estimate the effect of the reform on the hazard rates into and out of unemployment, the analogue of differences-in-differences is estimated using a formal hazard model. I estimate an exponential model that controls for observables and includes, the formal dummy, the post-1990 dummy and the interaction term between the formal and the post-1990 dummy:

$$h(s_{it} | \mathbf{X}_{it}, ) = \exp \{ \boldsymbol{\beta} \mathbf{X}_{it} + \delta_0 \text{Formal}_{it} + \delta_1 \text{Post90}_{it} + \delta_2 \text{Formal}_{it} \times \text{Post90}_{it} \},$$

where  $\mathbf{X}_{it}$  is a  $1 \times k$  vector of regressors, and  $\boldsymbol{\beta}$  is a  $k \times 1$  vector of parameters. The vector of covariates  $\mathbf{X}_{it}$ , includes: age, education, sex, marital status, number of dependants, the city where the person lives, and industry of employment. The Formal variable is included to control for constant differences between the groups. Thus,  $\delta_0$  is expected to be negative since the dismissal of formal workers is more costly than that of informal workers, both before and after

---

<sup>13</sup> Moreover, even if trends do not change by a common factor in both groups, an unconventional differences-in-differences estimator could be obtained using a method proposed by Heckman and Robb (1985). This method assumes that a pre-reform model, that is stable over time, could be fit for each group and then used to quantify post-reform shocks that can be inserted into equations fit to post-reform data.

the reform. The Post90 dummy controls for common shocks affecting the turnover behavior of all workers after 1990. Finally, the interaction term of the Formal and Post90 dummies is included to estimate the effect of the reduction in firing costs introduced by the reform on the hazard rates. A test of the impact of the reform is equivalent to a test that the coefficient on the interaction term,  $\delta_2$ , is different from zero. In particular, the test considers whether workers covered by the legislation changed their turnover behavior relative to uncovered workers after 1990.

## **B. Potential Sources of Contamination**

The identification strategy above exploits both the temporal variability and the cross-section variability available in the Colombian context. Nonetheless, these differences-in-differences estimators rely on a number of assumptions that may yield inconsistent estimates of the effects of firing costs on turnover. First, the differences-in-differences estimators ignore the general equilibrium effects of a reduction in firing costs on composition suggested by the model in the previous section. Second, the estimators rely on the assumption that trends did not change differentially across groups over time. In turn, I consider the implications for the identification of the firing cost effect of having these two potential sources of biases.

As highlighted by the model in the previous section, the reduction of firing costs introduced by the reform is likely to have generated general equilibrium effects. In particular, the model above showed that a reduction in firing costs not only has direct effects on turnover by reducing the costs of dismissals, but it also has indirect effects on turnover through its impact on sector selection. As described above, the differences-in-differences estimator above is consistent as long as self-selection is constant over time. The model in the previous section showed, however, that a reduction in firing costs changes the incentives to sort into the formal and

informal sectors and generates compositional changes that also affect turnover. Thus, a reduction in firing costs may itself generate compositional changes that invalidate the assumption of a constant self-selection rule, before and after the reform. Yet, the model above does suggest that the bias introduced by differences-in-differences should be negative. In the model, the reduction in firing costs induces firms with low firm-specific productivities to start producing formally and the reallocation between sectors thus lowers the average firm-specific productivity and increases turnover in both sectors. However, the effect of this change in composition on turnover was shown to be greater in the informal sector. Thus, while the firing cost effect obtained with differences-in-differences is inconsistent, the estimate should be a lower bound of the effect of the reduction in firing costs on turnover. Moreover, the next section shows that the change in the size of the two sectors was small and this may indicate that the selection bias is unlikely to be large.

The second reason why the differences-in-differences estimators may yield inconsistent estimates of the firing cost effects is if the trends change differently over time for formal and informal workers. As discussed above, an important assumption that has to be fulfilled for differences-in-differences to yield consistent estimates of the reform is that it eliminates the effect of aggregate shocks or trends on turnover. The effect of aggregate shocks is eliminated if aggregate shocks are common to both groups, or if aggregate shocks are specific to each group but either, the shocks are constant over time or the shocks change similarly across groups. However, if trends are different across groups and they change differently over time, the firing cost effects obtained from differences-in-differences are likely to be biased. Aside from macro shocks, which are common to both groups, there were two additional shocks occurring during this period that could have affected by turnover. First, trade was liberalized during this period

and, second, a social security reform was introduced in the early 1990's.

Colombia's trade liberalization during the early 1990's should be expected to have increased instability for workers employed in tradable sectors after 1990. Nonetheless, trade shocks should have affected formal and informal firms alike and, hence, differences-in-differences should control for the effect of these shocks on turnover. If, however, formal firms were more likely to produce in tradable sectors and informal firms in non-tradable sectors, then differences-in-differences would yield upwardly biased estimates of the firing cost effect. Below, I estimate differences-in-differences across sectors to identify whether the changes in turnover were greatest in tradable sectors. There are two reasons to believe, however, that the trade shocks did not generate the differences in turnover over time presented below. First, the next section shows no consistent pattern across sectors in the differences-in-differences estimates. In addition, differences-in-differences for different firm sizes and age groups show that the change in turnover was greatest for large firms and middle age workers who should have been affected most by the changes in job security legislation, but not by trade shocks.

The social security reform introduced during the early 1990's affected formal firms but not informal firms. Thus, the social security reform introduced a shock affecting formal and informal firms differentially over time. As described above, the social security reform increased employers' health and pension contributions and, thus, increased non-wage labor costs for firms complying with the legislation. The increased variable costs should have reduced hiring and should have had no effect on dismissals in the formal sector relative to the informal sector. This means that the social security reform should have generated very different effects on turnover

from those predicted by a reduction in firing costs and from those reported in the next section.<sup>14</sup> Moreover, if firms adjusted to the increased non-wage labor costs by reducing wages, then the social security reform should not have had any turnover effects. There is evidence that employers tend to pass on their non-wage costs to workers as lower wages. For example, Gruber (1997) shows the sharp reduction payroll taxes that followed the privatization of Chile's social security system had no employment effects because wages adjusted fully to the change in non-wage costs. Moreover, differences-in-differences across different firm sizes and age groups show that turnover changed most among larger firms and middle age workers who should have been affected most by the changes in job security legislation, but not by the social security reform.

## **VI. Empirical Analysis**

This section examines the impact of the Colombian labor market reform of 1990, which included a substantial reduction in severance payments, on the hazard rates out of employment and out of unemployment of formal sector workers relative to informal sector workers.

### **A. The Data**

#### **A.1 Description**

The data to analyze the effects of the reform on the exit rates out of employment and out of unemployment are drawn from the Colombian National Household Surveys (NHS) for June of 1988, 1992, and 1996. The June NHS's were administered in seven metropolitan areas, including: Barranquilla, Bogota, Bucaramanga, Cali, Manizales, Medellin, and Pasto. The benefit of using the June surveys is that these include information on informality that allows to

---

<sup>14</sup> See Kugler, Jimeno and Hernanz (2003) for an analysis of the differential effects of firing costs and payroll taxes on turnover and employment.

separate workers between formal sector workers (covered) and informal sector workers (uncovered). The June surveys allow defining workers as covered and uncovered in two ways. First, formal (covered) workers are defined as those workers whose employers make social security contributions and informal (uncovered) workers are defined as those whose employers do not contribute to the social security system. This definition is a useful one, because whether the employer contributes or not to social security is a good proxy of whether the employer generally complies or not with labor legislation. Second, formal (covered) workers are defined as wage-earners employed in firms with more than ten employees, and informal (uncovered) workers as wage-earners employed in firms with less than ten employees, family workers, domestic workers and the self-employed workers (excluding professionals and technicians). As discussed above, employers with five or less employees, family workers, and the self-employed are all exempt from severance pay legislation and domestic workers and workers in firms with low levels of capital are entitled only to half the amount of severance pay received by other employees. These surveys also include information on gender, age, marital status, educational attainment, number of dependents, city and sector of employment, that allows controlling for differences in turnover due to differences in characteristics across individuals. In addition, the surveys include information about whether the worker is permanent or temporary, which allows distinguishing the effect that the legislative change on temporary contracts had on turnover.

Table 3 presents summary statistics for the covered and uncovered groups (using the two definitions), before and after the reform. Columns 1 and 2 present the characteristics of formal (covered) workers and Columns 3 and 4 present the characteristics of informal (uncovered) workers, before and after the reform, respectively. Under both definitions, covered workers have more education, are slightly younger, have larger families, and are more likely to be married and

female and to have a permanent contract than uncovered workers. However, aside from the differences in educational attainment, the differences in characteristics between the two groups are small. In addition, the changes in characteristics of the two groups between the pre-1990 and the post-1990 periods have moved in the same direction and are similar in magnitude. Educational attainment, average age, and the share of married workers increased in both groups after 1990, while the share of men, the size of households, and the share of workers with permanent contracts decreased in both groups after 1990.

These summary statistics suggest that differences in composition between the groups are not substantial. Nonetheless, the differences in characteristics may account for part of the changing turnover patterns and, thus, raw differences in turnover between covered and uncovered groups should be interpreted carefully. For this reason, in the analysis below I estimate formal hazard models that allow controlling for individual characteristics. The use of these models is, thus, crucial for identifying the firing cost effect of the labor market reform. Another source of compositional bias may arise if, as highlighted by the model, the composition of firms changes over time. Table 3 shows an increase in the size of the formal (covered) sector after 1990, according to both definitions. The percentage of workers in the formal sector increased from 44.84% to 51.05%, according to definition 1, and from 41.47% to 45.22% according to definition 2, between the pre- and post-reform periods. The increase in the size of the formal sector, thus, indicates the importance of controlling also for firm characteristics, as the composition of formal firms may have also changed. Although the NHS's have little information on firm characteristics, the hazard models below do control for industry affiliation. Moreover, the fact that the increase in the size of the formal sector was small and that it cannot

be directly attributed to the reform suggests that the selection biases described above may not be of great concern.

## A.2. Sampling Plan

The June NHS's include information on tenure on the current job (in years) and on the duration of unemployment (in months) right before entering the current job that allow estimating hazard rates. In particular, the survey asks currently employed workers: How long have you been working on your current job?, and How long were you unemployed between your current job and your previous job? The data, thus, provides information on *incomplete* employment spells of *currently employed workers*, and on *complete* unemployment spells of workers who are *currently employed and had a previous job* (see graph below).

### June Waves:

The stock sampling for the employment spells generates two types of biases. First, the sampled employment spells are too short because of the sampling of *incomplete* employment spells. In particular, Heckman and Singer (1985) show that under the assumptions of a time homogenous environment, no heterogeneity, and independence between employment and unemployment spells, the completed spells would be on average twice as long. Second, as a consequence of sampling *currently employed* workers, the incomplete employment spells are

*longer* than the completed spells from a sample that follows workers flows from job-to-job over time. Thus, the sampling of currently employed workers introduces *length bias*. Heckman and Singer (1985) show, however, that under the assumptions stated above and, in addition, under the assumption of no duration-dependence the two biases exactly cancel out. Below, I estimate exponential hazard models that impose these assumptions.

Similarly, the stock sampling of the unemployment spells may also introduce a number of biases. Although the data provides complete unemployment spells, the fact that the spells are drawn from a sample of workers who are *currently employed and had a previous job* may generate biased estimates. First, sampling *currently employed* workers introduces length bias. This is because one oversamples workers with short spells relative to long spells. Thus, the mean of the sampled spells would be shorter than the mean of the spells from a flow sample. Second, sampling workers who *had a previous job* excludes all new entrants into the labor force and this introduces another type of length bias. By excluding new entrants from the sample, one oversamples workers with long spells relative to short spells, implying that the mean of the sampled spells would be shorter than the mean of the spells from a flow sample. Although, the distribution of unemployment spells obtained from this sampling plan is likely to be distorted, the bias due to stock sampling may be small in practice because the two biases have opposite signs and they may thus cancel out.

## **B. Tenure and Unemployment Spells, Before and After the Reform**

### ***Average Tenure***

The model presented above indicates that the direct and indirect effects of the reduction in firing costs introduced by the reform should have increased the exit rates out of employment for formal workers relative to informal workers. The reform should have, thus, reduced the

average tenure of workers covered by the reform (formal workers) relative to the tenure of uncovered workers (informal workers).<sup>15</sup>

Table 4 presents the average tenure for the covered and uncovered groups (using the first definition), before and after the Colombian Labor Market Reform of 1990.<sup>16</sup> The first row corresponds to the average tenure after the reform, the second row corresponds to the average tenure prior to the reform, and the third row to the differences. The last row provides the differences-in-differences estimate of the effect of the reform on tenure. The average tenure of covered workers decreased after the reform from 5.6002 to 5.3130 years. The decrease in average tenure for covered workers was of 3.4452 months and significantly different from zero. In contrast, the decrease in average tenure for uncovered workers was of 0.2112 months and not significantly different from zero. The differences-in-differences estimate of the effect of the reform was a reduction in average tenure of 3.6612 months. The effect is large, significantly different from zero, and, as predicted by the theory, most of the change comes from the reduction in average tenure of covered workers rather than from the increase average tenures of uncovered workers. Table 5 presents the difference-in-differences estimates of the reform on average tenure by gender. This table shows that most of the change in the aggregate figures is driven by the effect of the reform on men's tenures. The differences-in-differences estimate of the effect of the reform was a reduction of 4.1208 months for men and of 2.1012 months for women, although the effect is not significantly different from zero for women.

Tables 6 and 7 present differences-in-differences estimates of the reform for different age and education groups. Table 6 shows that the effect of the reform was greatest for middle age

---

<sup>15</sup> In particular, the average tenure of formal workers should decrease because the fraction of workers with short tenures (those just hired) increases and/or the fraction of workers with long tenures (those just fired) decreases.

<sup>16</sup> This section and the rest of the analysis relies on the first definition of formal/informal since the two measures are highly correlated and the

workers. The differences-in-differences estimate of the effect was a reduction of 4.0176 months for middle age workers, while the estimates for young and older workers were not significantly different from zero. These results are consistent with the change in severance pay legislation and with the change in ‘unjust’ dismissal legislation that raised the cost of ‘unjustly’ dismissing workers with more than ten years of tenure. In particular, the change in the legislation should have induced firms to dismiss workers just prior to completing ten years of tenure. This result is confirmed in the next section with the formal hazard analysis. In contrast, Table 7 shows that the difference-in-differences estimates of the effects of the reform were greatest for employees with primary education and with a university degree or more. This result, however, inverts in the formal hazard analysis that controls for changes in turnover for these groups after the reform.

Table 8 shows the differences-in-differences estimates of the effect of the reform by sector, to identify whether the reduction in tenures could have been the result of trade liberalization. This table shows that the difference-in-differences estimates for agriculture, mining, manufacturing, construction, and commerce are not significantly different from zero at conventional levels. Moreover, the differences-in-differences estimate of the reform was a reduction of 6.4836 months in transportation, but only significant at the 10% level, a reduction of 10.7028 months in financial services, only significant at the 5% level, and a reduction of 10.236 months in services, significant at the 1% level. Thus, the estimates by sector do not show a consistent pattern of changes across tradable and non-tradable sectors. These results are confirmed by the formal hazard analysis presented below. Moreover, consistent with the changes predicted by the labor market reform, the changes that are significant are driven by

---

results are robust to the definition used.

reductions in the tenures of covered workers and not by the increase in tenures of uncovered workers.

Table 9 shows the differences-in-differences estimates by firm size. The results show that the effects of the reform were greatest for larger firms, as predicted by the changes in the legislation. The differences-in-differences estimates for the self-employed and for workers employed in firms with 2-5 employees and in firms with 5-10 employees are not significantly different from zero. In contrast, the estimate of the effect of the reform for workers employed in firms with more than ten employees was a reduction of 6.3372 months. The effect of the reform on workers employed by large firms is big, significantly different from zero, and driven mainly by a reduction of tenures of covered workers rather than by an increase of the tenures of uncovered workers. This evidence is strongly consistent with the expected effects of a reduction in firing costs, since the self-employed and workers employed in firms with less than 5 employees are completely exempt from severance and workers employed in firms with little capital are only entitled to partial severance payments.

### ***Unemployment Duration***

The model predicts that a reduction in dismissal costs should increase the exit rate out of unemployment and into formal jobs relative to the exit rate out of unemployment and into informal jobs. Thus, the reduction in severance payments would be expected to shorten unemployment spells of workers hired into formal jobs relative to those of workers hired into informal jobs.<sup>17</sup>

---

<sup>17</sup> In particular, the average unemployment spell of those going into formal jobs should decline because of the increased probability of being hired into a formal firm should reduce the fraction of workers with long spells. Moreover, the fraction of workers with short spells (those just fired from formal jobs) increases.

Table 10 presents the differences-in-differences estimates of unemployment spells.<sup>18</sup> The average unemployment spell for workers whose spell ended with a formal sector job increased. However, the average unemployment spell of workers whose spell ended in an informal sector job lengthened by even more than that of formal workers. Thus, the differences-in-differences estimate was a reduction in the average unemployment spell of 3.1108 weeks and significantly different from zero.<sup>19</sup> Table 11 presents the results for men and women, separately. The differences-in-differences estimate for men was not significantly different from zero, but the effect on women was a shortening of the average unemployment spell of 7.9672 weeks and significant at the 1% level. Table 12 presents the differences-in-differences estimates for different age groups and Table 13 presents the differences-in-differences estimates for different education groups. The results show that unemployment spells decreased most for young and middle aged workers. This result is consistent with the expectation that a decrease in firing costs should increase hiring, especially for outsiders, and is also confirmed in the formal hazard analysis below. Moreover, Table 13 shows that the differences-in-differences estimates are greatest for workers with incomplete secondary and incomplete university education. Thus, the firing cost effect on hiring appears to be greater on workers that are risky hires. This is also confirmed below by the formal hazard analysis.

Table 14 presents the differences-in-differences estimates of the effect of the reform on unemployment spells by industry. The differences-in-differences estimates are not significantly different from zero in agriculture, mining, manufacturing, utilities, construction, transportation,

---

<sup>18</sup> Unemployed workers are defined as formal if the job subsequent to their spell was in the formal sector and as informal if their job subsequent to the spell was in the informal sector.

<sup>19</sup> Contrary to the results for tenure, the differences-in-differences results for unemployment spells are driven mainly by the lengthening of the spells of those exiting into the informal sector. This is however, consistent with the model presented above. On the one hand, the model predicts that the probability of being hired in the formal sector should rise after the reform because of the increase in the number of firms producing in this sector. On the other hand, the probability of being hired into the informal sector falls unambiguously.

and financial services. Only the effect on commerce and services are significantly different from zero. The differences-in-differences estimate of the effect of the reform was a reduction of 1.2746 weeks of the unemployment spell in commerce, but only significant at the 5% level and a reduction of 1.3126 weeks of the unemployment spell in services, significant at the 1% level. Thus, as for tenure, the results do not show a consistent pattern of a differential impact on tradable and non-tradable sectors. In contrast, the differences-in-differences estimates by firm size in Table 15 provide some evidence that the firing cost effect was greatest among larger firms. In particular, the differences-in-differences estimates of the reform on firms with 5 –10 employees and on firms with more than ten employees indicate reductions of the average unemployment spell of 0.8038 weeks and of 0.2913 weeks, respectively. Although neither effect is significant at conventional levels, the p-values for the differences-in-differences estimates of larger firms are greater than the p-values for the estimates of the self-employed and of firms with 2-5 employees.

### **C. Employment and Unemployment Survivor Functions, Before and After the Reform**

While the previous section presented the implied effects of the reform on tenure and unemployment spells, this section presents evidence on the effects of the reform on the survival probabilities in employment and unemployment. If the reduction of dismissal costs introduced by the reform, indeed, was important, then the probability of survival in a formal job should had fallen after the reform relative to the probability of survival in an informal job. In addition, if the reduction in dismissal costs generated more hiring, then the probability of survival in unemployment should had fallen after the reform for workers exiting into formal jobs relative to those exiting into informal jobs.

Figure 1 presents the Kaplan Meier survival estimates for employment. This figure includes the probabilities of survival for formal and informal workers before and after the reform. The figure shows that the probability that a formal job lasts more than two years decreased after the reform. For tenures of more than two years, the survivor function of formal workers after the reform (Formal/Post-1990) shifts down with respect to the survivor function of formal workers before the reform (Formal/Pre-1990). However, for tenures of less than two years, the survivor function of formal workers after the reform shifted up with respect to the survivor function of formal workers before the reform. That survivor function is greater for formal workers with less than two years of tenure after the reform is surprising, given the extension by the reform of the use of temporary contracts for less than a year. However, this shift in the survivor function for those with less than two years of tenure may simply reflect the greater hiring of new permanent workers after the reform, as is shown below in the estimation of formal hazard models. The downward shift of the survivor function of formal workers after the reform is consistent with the reduction in dismissal costs for formal firms after the reform. In contrast, however, Figure 1 shows, that the probability of survival increased slightly for informal workers after the reform relative to informal workers prior to the reform. The survivor function of uncovered workers after the reform (Informal/Post-1990) shifted up slightly with respect to the survivor function of uncovered workers before the reform (Informal/Pre-1990). If common shocks to both groups were responsible for the decreased probability of survival of formal jobs, then the figure should also show a downward shift of the survivor function for informal workers. Moreover, consistent with the fact that formal workers are covered by job security regulations while informal workers are not, the survivor functions for formal workers are higher than the survivor functions of informal workers both before and after the reform. The survivor functions

for the covered and uncovered groups, as well as the shifts of the survivor functions for each group after the reform, are, thus, consistent with the predicted effects of firing costs and with the predicted effects of the reform on formal turnover.

Standard Kaplan-Meier survival functions of unemployment show a similar change after the reform. Figure 2 shows that the unemployment survival functions of formal hires shifted down between the pre-reform (Formal/Pre-1990) and post-reform (Formal/Post-1990) periods. Thus, for every unemployment spell of duration  $t$ , the probability of remaining unemployed decreased after the reform for those who exited into formal employment. On the contrary, Figure 2 shows that the unemployment survival functions increased slightly for informal workers, after the reform. These shifts are consistent with the expected effects of the reform. The reduction of firing costs would have predicted that the probability of remaining unemployed at every time  $t$  should have decreased for workers covered by the reform but not for uncovered workers. Moreover, the next section shows, that the escape rates into and out of unemployment increased for formal workers relative to informal workers, even after controlling for observable characteristics.

#### **D. Formal Hazard Models**

It is possible that the employment and unemployment spells and the survivor functions presented above changed after the reform due to changes in the characteristics of workers and jobs after 1990. Thus, below I estimate formal duration models that allow controlling for the effects of changes in worker and job characteristics on exit hazard rates.

As described in Section IV, I estimate exponential hazard models that control for age, education, marital status, city, industry of employment, and the number of dependents. More importantly, these formal hazard models can capture the effects of the reform. The models

include a Formal dummy that controls for differential turnover patterns across groups, a Post90 dummy that captures the differential turnover pattern in turnover after 1990 for all groups, and an interaction term of the Formal and Post90 dummies that captures the effect of the reform. In particular, the coefficient of the interaction term can be interpreted as the differential hazard rates of covered workers after the reform was introduced. Moreover, to further probe the importance of the reform, other specifications of the model are included to test whether the effects of the reform showed the expected patterns for different groups. In addition, to test the importance of trade shocks, a specification of the model that includes interaction terms of the Formal  $\times$  Post90 dummy with sector dummies is also estimated.

Table 16 shows the results of the estimation of exponential exit hazard rates out of employment. Column (1) presents the estimates obtained from the basic specification of the model that includes the covariates mentioned above, the Formal dummy, the Post90 dummy, and the interaction term of the two. The results show the expected signs. The hazards are higher for younger, more educated, female, and single workers and for workers with smaller number of dependents. The results also show that the hazards out of employment decreased during the post-1990 period for informal workers. Moreover, as expected, formal workers, who are covered by the legislation, have lower hazards out of employment than do informal workers. Most importantly, the coefficient on the interaction term is positive and significant at the 1% level. In particular, the coefficient indicates that, after the reform, covered workers are 6.17% more likely to exit employment than are uncovered workers. This result, thus, suggests that the reduction in firing costs introduced by the reform increased the exit rates out of employment substantially. Exit hazards out of employment are likely to have increased after the reform both because of the

increase in dismissals and because of the increase in quits resulting from greater hiring after the reform.

Another essential feature of the reform was the greater flexibility in the use of temporary (fixed-term) contracts and, thus, one may suspect that a great deal of the increases in turnover after the reform may simply be the result of increased hiring of temporary workers in the formal sector. The specification in Column (2) allows to distinguish whether the increase in the exit rates out of employment was purely the result of the increase in the use of temporary contracts or if the reduction in the cost of firing permanent workers also played a role. Column (2) in Table 16 presents the estimates of a model including, a permanent dummy, an interaction term of the Post90 dummy and the permanent dummy, an interaction term of the Formal dummy and the Permanent dummy, and an interaction of the Formal  $\times$  Post90 dummy with the Permanent dummy.<sup>20</sup> All the coefficients have the same signs as before and the coefficient on the Permanent dummy is negative and significant at the 1% level, as expected. The results show that the coefficient on the Formal  $\times$  Post90 interaction is positive, but the interaction term of the Formal  $\times$  Post90 dummy with the Permanent dummy is negative and significant at the 1% level. The results indicate that, after the reform, the probability of exiting employment was 6.7% higher for temporary workers in the formal sector than for temporary workers in the uncovered sector. At the same time, the probability of exiting employment was 6.1% higher for permanent worker in the formal sector than for permanent workers in the uncovered sector after the reform. Thus, while the introduction of temporary contracts does appear to explain part of the increased turnover of formal workers, the results also suggest that the reduction of dismissal costs for permanent workers also contributed to increasing turnover.

Column (3) in Table 16 presents the results of specifications including interaction terms of the reform effect with the age and education variables. This specification of the model allows seeing whether the impact of the reform was greater on the groups that would be expected to be affected most by the changes in the legislation. First, since the reform increased the costs of dismissing workers with more than ten years of tenure, then the impact of the reform would be expected to be greater for groups with less than ten years of tenure (i.e., younger workers). Second, the special contracts introduced by the reform, which exempted workers with more than ten times the minimum wage from severance payments, would be expected to affect mostly the turnover of highly educated workers who are likely to earn more than ten times the minimum wage. Column (3) shows that, indeed, the hazard rates of younger and middle-aged workers increased by more than the hazards of older workers. Young workers with secondary education hired in the formal sector were 4.1% more likely to exit employment than did younger informal workers with secondary education after the reform. Similarly, middle-aged formal workers with secondary education were 7.9% more likely to exit employment than did middle-aged informal workers with secondary education after the reform. The smallest impact of the reform was on older formal workers, who were only 1.8% more likely to exit employment than did older informal workers after the reform. These results are thus consistent with lower expected dismissals of workers with more than ten years of tenure. Moreover, the results also indicate that the impact of the reform was greater on more educated workers who are more likely to have benefited from the use of “Integral Salary” contracts. The exit rate of middle-aged formal workers with a primary education increased by 6.6% after the reform relative to middle-aged informal workers with the same level of education. The exit rate of middle-aged formal workers

---

<sup>20</sup> The permanent dummy takes the value of 1 if the worker is a permanent worker and zero if the worker is temporary.

with secondary, a high school degree and university education increased by 7.9%, 12.5%, and 13.1% after the reform relative to middle-aged informal workers with the same levels of education. In contrast, the hazard out of employment increased only by 3.8% for middle-aged formal workers with more than a university degree after the reform relative to middle-aged informal workers with the highest educational attainment. The impact was, thus, smallest among the least and the most educated. The small impact on these groups may be due to the fact that these workers have longer tenures and, thus, are more likely to have been affected by the increase in the costs of ‘unjust’ dismissals for tenures of more than ten years.

While the above patterns are consistent with the effects of the labor market reform on different groups, it may be that part of the increased turnover is the result of trade shocks affecting various groups differently. Column (4) in Table 16 presents the results from an exponential hazard model that includes interaction terms of the Formal  $\times$  Post90 dummy with sector dummies. The idea is that if trade liberalization were responsible for the increased turnover after the labor market reform, then the observed impact would be greater on workers employed in tradable sectors than on those employed in non-tradable sectors. The results from Column (4) in Table 16 show that the increase in turnover of covered workers after the reform was greater in utilities, transportation, construction and services. The probability of exiting formal employment in these sectors after the reform was 640%, 15.7%, 12.3%, and 17.6% greater than the probability of exiting informal employment in these sectors. However, if the trade shocks were a main source of the increased turnover, it would be expected that the exit rate out of employment would have increased more for workers hired in trade-intensive sectors such as commerce and manufacturing. In fact, after the reform formal workers in commerce were only 2.5% more likely to exit employment than informal workers in this sector were. Moreover,

the probability of exiting employment was 1% lower after the reform for formal workers relative to informal workers hired in manufacturing. The results from the exponential hazard model, thus, do not provide any reason to believe that trade liberalization increased turnover for covered workers after 1990.

Table 17 includes the results of exponential hazards out of unemployment. Given the reduction of mandated firing costs, one would expect greater hiring in the covered sector and, thus, an increase in the escape rate out of unemployment for workers hired into formal sector jobs. Column (1) shows that, indeed, the exit hazard out of unemployment increased by 5.75% for covered workers after the reform relative to uncovered workers.<sup>21</sup> Moreover, while the extension of temporary contracts appears to explain part of the increased hiring, most of the increase in the exit hazards out of unemployment is due to the increased hazards into permanent jobs in the formal sector. The results from Column (2) in Table 17 show that the escape rate out of unemployment increased by 4% for formal temporary workers after the reform relative to temporary informal workers. However, the exit rate out of unemployment increased by even more for formal permanent workers after the reform, thus indicating that the reduction in dismissal costs of permanent workers did increase the incentives to hire this type of workers. The results show that the probability of exiting unemployment and entering a formal permanent job increased by 6.1% after the reform relative to the probability of entering an informal permanent job.<sup>22</sup>

Column (3) in Table 17 presents the results of the exponential hazard model including interaction terms of the reform effect with the age and education variables. The estimates from

---

<sup>21</sup> The sign on the formal dummy is positive and significant at the 1% level. This could be explained if unsuccessful discouraged workers who get tired of searching for formal work turned to the informal sector as a last resource.

this model show that, as for the hazards out of employment, the impact of the reform was greater on younger and more educated workers. The reform should have had greater effects on the exit rates out of unemployment for younger workers if the reduction in dismissal costs decreased the power of insiders and induced more hiring of young outsiders. In fact, the exit rate out of unemployment and into formal jobs for young workers increased by 25.8% after the reform relative to the exit rate into informal jobs. The exit rate into formal jobs for middle-aged workers also increased after the reform but not by as much. In particular, the hazard rate out of unemployment and into formal jobs increased by 3.9% for middle-aged workers relative to informal workers. In contrast, the hazard rates out of unemployment and into formal jobs decreased by 11.1% for older workers after the reform, relative to those entering informal jobs. In addition, these results show that the impact of the reform on exit hazard rates out of unemployment was greatest on the more educated. This is to be expected, given that these workers are the ones more likely to opt for the “Integral Salary” contract that exempts workers from severance and other dismissal costs. In fact, the hazards out of unemployment and into formal jobs decreased after the reform by 10% relative to the hazard out of unemployment and into informal jobs for workers with primary education and by 3.9% and 1.2% for workers with secondary schooling and a high school degree, respectively. In contrast, after the reform, the exit rates out of unemployment and into formal jobs increased by 37% for university graduates and by 12% for workers with more than a university degree relative to the exit rates into informal jobs.

Finally, Column (4) in Table 17 shows the results of the hazard model with sector dummy and reform interactions. The results show that the increase in the exit rates out of

---

<sup>22</sup> The sign on the permanent dummy is positive and significant at the 1% level. Similarly to the description in footnote 17, this is probably due

unemployment after the reform was greater for workers exiting into formal sector jobs in mining, utilities, and services. The probability of exiting unemployment into formal employment in these sectors after the reform was 45.7%, 27.6%, and 10.9% greater than the probability of exiting unemployment into informal employment in these sectors. However, the probability of exiting unemployment into formal employment in trade-intensive sectors such as commerce and manufacturing was only 2.8% and 6.7% higher than the probability of exiting unemployment into informal employment in these sectors. As the results from the employment hazard models, these results from the unemployment hazard model, thus, do not provide evidence indicating the importance of trade liberalization in increasing worker turnover after 1990. Instead, the increased hazards in utilities and services, which are more likely to be public sector jobs covered by the legislation, indicates to the importance of the labor market reform in generating these patterns in turnover.

## **VII. Worker Turnover and Unemployment**

The previous section showed that the functioning of labor markets changed substantially in Colombia after the introduction of the labor market reform of 1990. In particular, the estimates from the formal hazards show that, after controlling for observable characteristics, the post-reform period was characterized by higher exit rates into and out of unemployment in the formal sector relative to the informal sector.

While the results in the previous section indicate that the reform increased labor market flexibility by increasing the flows into and out of unemployment, the net effects of the reform on employment and unemployment are ambiguous. In this section, I use the steady state condition of the model in Section IV, together with the hazard rate results obtained in Section VI, to obtain

---

discouraged workers who are unsuccessful finding a permanent position turning to temporary jobs as a last resource.

a rough estimate of the net effect of the reform on unemployment.

In the model above, a steady state condition has to be satisfied such that the flow into unemployment from both sectors must equal the flow out of unemployment and into both sectors:

$$\lambda_F e_F + \theta q(\theta)(1-F(A_m))G(\bar{\gamma}_F)u + \lambda_I e_I + \theta q(\theta)F(A_m)G(\bar{\gamma}_I)u = \theta q(\theta)(1-F(A_m))u + \theta q(\theta)F(A_m)u.$$

Substituting for employment in each sector,  $e_F = (1-F(A_m))e$  and  $e_I = F(A_m)e$ , and for the identity,  $e + u = 1$ , and solving for  $u$  yields the following formula for the unemployment rate,

$$u = [(1-F(A_m))\lambda_F + F(A_m)\lambda_I] / [(1-F(A_m))\lambda_F + F(A_m)\lambda_I + (1-F(A_m))\theta q(\theta)(1-G(\bar{\gamma}_F)) + F(A_m)\theta q(\theta)(1-G(\bar{\gamma}_I))].$$

The unemployment rate can be estimated from this equation by substituting for the average hazard rates into and out of unemployment during the pre-reform period and the shares in each sector. The average hazard rates are estimated with the average tenure and unemployment spells in Tables 4 and 10, which indicate an average tenure of 67.2 and 54.2 months in the formal and informal sectors and average unemployment spells of 1.8 and 2.2 months in the formal and informal sectors during the pre-reform period. The shares of formal and informal employment are reported in Table 1. Before the reform, the shares of formal and informal employment were 0.45 and 0.55, respectively. After the reform, the shares of formal and informal employment changed to 0.51 and 0.49, respectively. Finally, Tables 16 and 17 show an increase in the hazards into an out of unemployment of 6.17% and 5.75%.

As the model abstracts from many factors affecting labor markets, the estimated unemployment obtained from the formula above should not be interpreted as precise estimates of the unemployment rate, but rather as an indication of the magnitude of the changes in unemployment rates between the two periods. For example, taking into account other flows such

as retirements, new entries into the labor market, and deaths, the unemployment rate is:

$$u = \frac{\xi + \psi + \sigma + (1-F(A_m))\lambda_F + F(A_m)\lambda_I}{\xi + \psi + \sigma + (1-F(A_m))\lambda_F + F(A_m)\lambda_I + (1-F(A_m))\theta q(\theta)(1-G(\bar{\gamma}_F)) + F(A_m)\theta q(\theta)(1-G(\bar{\gamma}_I))},$$

where  $\xi$ ,  $\psi$ , and  $\sigma$  are the flows due to retirements, new entries, and deaths, which are estimated assuming a working life of 35 years, entry at 18 years of age, and a life expectancy of 60 years for those that die before retiring.

The unemployment rate for the pre-reform period obtained with this formula is 4.84%, which is lower than the true unemployment rate of 11.8% in Colombia in 1988. The post-reform unemployment rate estimated with the post-reform shares is 4.69%, which is also a lower than the true unemployment in 1992 and 1996, 10.2% and 10%, respectively. These results suggest a reduction in unemployment of 0.15% points between the pre- and post-reform periods, compared to the actual reduction in unemployment of 1.6% between 1988 and 1992 and of 1.8% between 1988 and 1996. These results suggest the reform contributed to about 10% of the reduction in the unemployment rate between the pre- and post-reform periods.

### VIII. Conclusion

The Colombian labor market reform of 1990 provides an interesting quasi-experiment to analyze the effects of a reduction in firing costs. This study exploited the temporal change in the legislation together with the difference in coverage between formal and informal workers to analyze the impact of the reform on worker turnover. The differences-in-differences estimates indicate that the reform increased the dynamism of the Colombian labor market, by increasing the exit rates into and out of unemployment. Moreover, aside from contributing to increase mobility in the labor market, the reform is also likely to have contributed to increase compliance with labor legislation by lowering the costs of formal production. The increased churning in the

labor market and the greater compliance with the legislation are estimated to have contributed to about 10% of the reduction in the unemployment rate from the late 1980's to the early 1990's. At the same time, the reform is likely to explain in part the recent surge in the unemployment rate during the late 1990's. This is because the greater flexibility in hiring and firing after the reform is likely to translate in increased hiring relative to firing during expansions but in increased firings relative to hiring during recessions.

Share of Married Workers	69.71%	72.43%	68.39%	73.09%
Average Education	8.93 years	9.79 years	6.29 years	6.95 years
Average Age	34.7 years	35.02 years	36.57 years	37.17 years
Average No. of Dependants	0.84 persons	0.77 persons	0.78 persons	0.73 persons

Notes: the table reports proportions and means of the variables in the formal and informal sectors before and after the reform using two alternative definitions of informality. The proportions and means using the first definition are presented in the top panel, while those using the second definition are presented in the bottom panel. Under definition 1, workers are defined as those whose employers pay social security taxes and informal workers are those whose employer does not pay social security contributions. Under definition 2, formal workers are defined as wage-earners employed by firms with more than 10 employees and informal workers are wage-earners employed by firms with less than 10 employees, family workers, domestic workers, and self-employed workers. In Colombia, family workers, self-employed, and workers employed by firms with less than 5 employees are completely exempt from severance pay legislation, while domestic workers and workers employed by firms with little capital are subject to half the severance payments of workers completely covered by the legislation.

# The Effects of Hiring and Firing Regulation on Unemployment and Employment: Evidence Based on Survey Data

**Abstract.** We use the results of surveys among senior business executives to measure the strictness of hiring and firing regulations. The survey data are more likely than objective indicators (used in almost all previous studies) to correctly capture the de facto strictness of these regulations and their relevance to the performance of the labor market. Using data from 19 industrial countries for the period 1992 to 2002, we find that more flexible regulations are likely to lower unemployment and to increase employment rates. While the effects on the general population appear to be modest, the effects on female, young and low-skilled workers seem to be substantial.

**JEL classification:** E24, J23, J63, J64, J68

**Keywords:** employment, employment protection, hiring and firing regulation, unemployment

## 1. Introduction

As is well known, the net effects of hiring and firing regulation on unemployment and employment cannot be unambiguously deduced from theory (see, e.g., Bertola 1990). Given the ambiguity of theoretical models, the direction and magnitude of the impact of hiring and firing regulations have to be resolved empirically. Although many empirical studies have analyzed their effects over the

1  
2  
3 past years, the evidence so far is mixed.<sup>1</sup> In recent surveys of the empirical literature, the OECD  
4 (2004a, p. 80), Layard et al. (2005, p. XVII) and Bassanini and Duval (2006, p. 89) conclude that  
5  
6 these studies do not settle the matter.  
7  
8  
9

10  
11  
12 This paper attempts to gain new insights by using a subjective indicator of the strictness of hiring  
13 and firing regulation. By contrast, almost all previous studies have used so-called objective  
14 indicators. These indicators have their limitations though. Hiring and firing regulations comprise a  
15 large number of statute laws, administrative orders and court decisions. It is very hard to develop an  
16 objective indicator that correctly reflects the strictness of all of these rules and regulations. Even if  
17 it would be possible to correctly measure the de jure strictness of hiring and firing regulations,  
18 objective indicators are unable to capture the de facto strictness of these regulations, which also  
19 depends on informal norms and the way the formal rules are enforced. The de facto strictness may  
20 vary through time, for example because of changes in the manner how courts and public  
21 administrations apply a given set of laws and regulations. Furthermore, objective indicators are  
22 unable to measure how employers judge the strictness of a given set of hiring and firing regulations.  
23 Employers' judgments, and their responses in terms of recruitment and dismissal of workers, may  
24 also vary through time, even with de jure strictness remaining unchanged. For example, suppose  
25 hiring and firing regulations have recently been liberalized in other economies, or other economies  
26 with more flexible regulations have recently become more open to trade and foreign direct  
27 investment. As a result, employers may conclude that domestic hiring and firing regulations have  
28 become relatively more burdensome. This may induce them to move jobs abroad, lowering  
29 employment and increasing unemployment in the domestic economy.

## 22 **2. Data**

23  
24  
25  
26

27 To measure the strictness of hiring and firing regulation, this paper uses results from the World  
28 Economic Forum's Executive Opinion Surveys (EOS), which are carried out annually in a large  
29 number of countries to determine the international competitiveness of the relevant economies. The  
30 respondents are a company's CEO or a member of its senior management. In each country  
31 approximately 60 to 70 executives are interviewed. The industry structure of the companies  
32 questioned corresponds largely to the industry structure of the relevant economy (excluding the  
33 agricultural sector). Also, care is taken to question companies of various size categories and types  
34 (e.g., private and state-owned, domestically oriented and internationally active enterprises).<sup>2</sup>

51  
52 <sup>2</sup> Over time, there have been some changes to the World Economic Forum's surveys that are of minor importance to our  
53 analysis. First, between 1989 and 1995 the surveys were conducted in collaboration with the Institute for Management  
54 Development, Lausanne, and between 1996 and 2001 in collaboration with the Center for International Development at  
55 Harvard University. Second, the number of countries covered has increased steadily from 36 in 1992 to 80 in 2002.  
56 (Due to a lack of data on some of our control variables, our empirical study covers only 19 industrial countries. See text  
57 and Appendix A for details.)  
58  
59  
60

1  
2  
3 The typical EOS question asks participants to indicate on a numerical scale which of the two  
4 statements specified in each case they favor. After the questioning, arithmetic means for each  
5 question are calculated from the answers for each country. The Box contains the questions on hiring  
6 and firing regulation used in the following analysis. The World Economic Forum used different  
7 scales in the years before 1997. For the purpose of our analysis, we converted all pre-1997 answers  
8 to the 1-to-7 scale used in the more recent surveys. The period covered by our empirical analysis is  
9 1992 to 2002. In the years prior to 1992, the respective questions were phrased very differently. For  
10 example, in 1991 the EOS statement read: “Flexibility of management to adjust employment levels  
11 during difficult periods: 0 = low, 100 = high” (World Economic Forum and Institute for  
12 Management Development 1991). Thus the question did not explicitly refer to hiring and firing  
13 regulations. In 1990 the EOS statement read: “Flexibility of enterprises to adjust employment and  
14 compensation levels to economic realities: 0 = not at all, to 100 = a great deal” (World Economic  
15 Forum and Institute for Management Development 1990). Similarly, in the years 1984 to 1987 and  
16 in 1989 (there was no survey in 1988), the EOS statement read: “Flexibility of enterprises to adjust  
17 job security and compensation standards to economic realities: 0 = none at all, to 100 = a great  
18 deal” (EMF Foundation – The World Economic Forum 1984, 1985, 1986; World Economic Forum  
19 1987; World Economic Forum and Institute for Management Development 1989). Thus before  
20 1991, the questions did not exclusively refer to adjustments in employment or job security (and thus  
21 at least implicitly to hiring and firing regulations) but also to wage adjustments. Because of these  
22 substantial differences, we excluded the answers to the pre-1992 questions from our data set. The  
23 questions from the Executive Opinion Surveys 1992 to 2002 explicitly refer to hiring and firing  
24 regulations and are all phrased in a similar way (see Box). There are some slight variations but these  
25 are only refinements of style to make the questions more precise. Thus the answers to all 11  
26 questions can be used simultaneously.<sup>3</sup>

---

<sup>3</sup> As higher marks on the EOS scale indicate more flexible regulation, we label our variable of interest ‘flexible hiring and firing regulation’.

There are a number of reasons to assume that the answers of the Executive Opinion Surveys correctly reflect the strictness of hiring and firing regulations and thus may be superior to objective indicators:

- First, the selection of respondents is largely representative and the respondents have comprehensive knowledge of and practical experience with the hiring and firing regulations of their countries.
- Second, the questions are phrased objectively and, at the same time, permit a better coverage of the various facets of hiring and firing regulations than hard data. For example, a country's dismissal regulations comprise a large number of legal standards, administrative orders and court decisions. If only the duration of the statutory notice period and the amount of the severance payment for a worker with ten years' length of service are used as indicators, as was the case with Lazear (1990), the degree of strictness of hiring and firing regulations is not completely and correctly measured. The OECD's (1999, 2004a) employment protection legislation (EPL) indicator, which has been used in almost all recent studies, is much more sophisticated than Lazear's (1990) indicator. Still, although the OECD's EPL indicator does an excellent job in measuring the de jure strictness of hiring and firing regulations, it is unable to capture their de facto strictness. As already pointed out, the de facto strictness also depends on the degree of enforcement of the law and on informal norms. For instance, in some countries, like France, advance notice before dismissal given orally is more important than the length of the notice period stated in the law. Informal norms and the degree of enforcement of the law cannot be captured at all by hard data. By contrast, the answers to the EOS questions appear to be well suited to capture the de facto strictness of hiring and firing regulations.
- Third, as the respondents decide on the recruitment and dismissal of workers, their answers are likely to reflect the relevance of the strictness of hiring and firing regulations to the performance of the labor market. In fact, the answers are likely to reflect this relevance better than objective

1  
2  
3 data. For instance, when deciding on whether to hire additional workers on a fixed-term basis,  
4  
5 the decisive aspect is neither the allowed maximum number of successive fixed-term contracts  
6  
7 nor their allowed maximum cumulated duration, as stated by the law (aspects measured by the  
8  
9 OECD's EPL indicator). What is decisive is whether the regulations on fixed-term contracts are  
10  
11 flexible enough in the opinion of those who decide on recruitment and dismissal. As pointed out  
12  
13 in section 1, employer's opinions are not only determined by domestic rules, formal and  
14  
15 informal, and the manner the rules are implemented in practice. They are also influenced by  
16  
17 (changes to) the international competitiveness of these rules. For example, if other economies  
18  
19 have recently relaxed their hiring and firing regulations, employers may conclude that the  
20  
21 domestic regulations have become relatively more burdensome, even if these regulations have  
22  
23 not changed. They may thus relocate jobs abroad, leading to lower employment and higher  
24  
25 unemployment in the domestic economy. Indeed, empirical studies have found that countries  
26  
27 with more flexible hiring and firing regulations are able to attract more foreign direct investment  
28  
29 (Cooke 1997, Görg 2005).  
30  
31  
32  
33  
34  
35  
36  
37  
38

39 Of course, potential drawbacks also have to be considered in connection with the use of the  
40  
41 Executive Opinion Surveys. One potential drawback is that the answers may be distorted by the  
42  
43 state of the business cycle prevailing at the time of the questioning. For example, the managers of a  
44  
45 country might judge the dismissal protection regulations favorably during a boom when they do not  
46  
47 have to lay off many workers. In a subsequent recession, when they do have to substantially reduce  
48  
49 staff, they might feel restricted by those regulations. Thus, they might then judge them less  
50  
51 favorably, although the regulations have not been altered in the meantime. However, a closer look  
52  
53 at the data suggests that the business cycle does not affect the EOS scores. A first indication is that  
54  
55 the correlation coefficient between the variable output gap and the EOS-based variable hiring and  
56  
57 firing regulation, at  $-0.21$ , is low and negative, not positive as could be expected if the EOS scores  
58  
59 would be affected by the business cycle in the way described previously. Furthermore, Table 1  
60

1  
2  
3 presents four different regressions with the output gap as an independent variable and flexible  
4 hiring and firing regulation as the dependent variable. Regressions (1) and (2) use the fixed effects  
5 method to control for unobserved country effects. In regression (1), the coefficient on output gap is  
6 statistically significant at the 1% level, but it is negative as well. If we add log income per capita to  
7 control for the impact of the level of economic development, the coefficient on output gap becomes  
8 statistically insignificant [regression (2)]. It remains statistically insignificant if we apply the  
9 random effects instead of the fixed effects method [regression (3)].<sup>4</sup> If we do not control for  
10 unobserved country effects but just for the level of economic development, the coefficient on output  
11 gap is statistically significant at the 1% level [regression (4)]. However, once again, it has a  
12 negative algebraic sign, contradicting the hypothesis that booms (recessions) lead to higher (lower)  
13 EOS scores. All in all, we can safely reject this hypothesis.  
14

25  
26  
27  
28  
29  
30  
31

32 A second potential drawback of the EOS data is that each respondent could use his own yardstick  
33 when answering the questions. For example, on the 1-to-7 scale, an item marked 7 by one person  
34 may only be marked 5 by another. This is a concern particularly because only 60 to 70 managers  
35 were interviewed in each country. However, in the planning, implementation and analysis of the  
36 surveys, care was taken to ensure the use of a uniform yardstick. For one, the respondents were  
37 provided with a written explanation of the answering scale. Also, the answers were examined for  
38 robustness and consistency using various methods. In one of these checks, half of the responses in  
39 each country were randomly dropped from the sample. As the national EOS scores remained stable  
40 in the process, they have obviously not been distorted by individual peculiarities in responding  
41 (Cornelius and Warner 2000, p. 94; Cornelius and McArthur 2002, pp. 169-173; Blanke et al. 2003,  
42 pp. 372-375).

58  
59  
60

---

<sup>4</sup> The Hausman test indicates that the random effects estimates may be biased (Table 1).

1  
2  
3 Another concern is that there may be a systematic bias among respondents at the national level. For  
4  
5 example, respondents in a country might have a similar biased assessment of the strictness of hiring  
6  
7 and firing regulation if this topic has recently been discussed extensively and with a certain flavor  
8  
9 in the press. Also, the questions may be interpreted differently in different countries. For these  
10  
11 reasons, the survey results may not accurately reflect differences in national hiring and firing  
12  
13 regulation. The authors of the Executive Opinion Surveys tried to avoid this problem by providing  
14  
15 all respondents with a written explanation of the answering scale and by asking them to think in  
16  
17 world terms rather than in national terms.  
18  
19  
20  
21  
22  
23

24 In order to check whether a “perception bias” exists, we compare the national EOS scores with  
25  
26 related hard data. As an objective indicator, we use the OECD’s (2004a) employment protection  
27  
28 legislation (EPL) indicator. This indicator measures the strictness of protection against individual  
29  
30 dismissals for workers with regular contracts and the strictness of regulation of temporary  
31  
32 employment (fixed-term contracts, temporary work agency employment).<sup>5</sup> As mentioned  
33  
34 previously, it solely uses objective data. For example, to measure the strictness of protection against  
35  
36 individual dismissal, it takes into account, inter alia, the length of the notice period and the amount  
37  
38 of severance pay at different lengths of tenure. To measure the strictness of regulation of temporary  
39  
40 employment, it takes into account, inter alia, the maximum number and the maximum cumulated  
41  
42 duration of successive fixed-term contracts as well as the maximum cumulated duration of  
43  
44 temporary work agency contracts. The OECD converted these measures into cardinal scores that  
45  
46 were normalized to range from 0 to 6, with higher scores representing stricter regulation. In  
47  
48  
49  
50  
51  
52

53  
54 \_\_\_\_\_  
55 <sup>5</sup> A second version of the EPL indicator additionally includes specific requirements for collective dismissals. However,  
56  
57 data for this broader indicator are only available since the late 1990s. This does not pose a major problem, though, as  
58  
59 specific requirements for collective dismissals do not play a major role. Indeed, as the OECD (2004a, p. 72) has  
60  
demonstrated, taking account of these specific requirements in the overall measure of EPL strictness does not affect  
cross-country comparisons much.

1  
2  
3 calculating the summary indicator of EPL strictness, it assigned the same weight to the regulation  
4 covering regular and temporary contracts.  
5  
6  
7  
8  
9

10 As hiring and firing regulations are usually reformed only rarely, most of the variation results from  
11 differences across countries rather than from changes through time. Thus we first calculate country  
12 averages for the EPL indicator and the EOS scores. Figure 1 plots the EPL indicator on the  
13 horizontal axis and the survey results on the vertical axis. The graph shows a strong relationship  
14 between the two variables. Indeed, the correlation coefficient for these country averages is  $-0.84$ .  
15 For example, the United States and the United Kingdom had both the lowest EPL scores and some  
16 of the highest EOS scores on average between 1992 and 2002. At the other end of the spectrum are  
17 Italy and Portugal, for example. On average between 1992 and 2002, these countries had both very  
18 high EPL scores and some of the lowest EOS scores. Thus in countries with strict (flexible) hiring  
19 and firing regulations, as measured by the EPL indicator, few (many) respondents thought that  
20 hiring and firing practices were flexibly determined by employers.  
21  
22  
23

31  
32  
33  
34  
35  
36  
37  
38

39 Figure 2 presents the corresponding correlation for the annual data. Unsurprisingly, the overall fit is  
40 somewhat weaker than for the country averages. Still, Figure 2 also indicates that higher (lower)  
41 levels of employment protection strictness, as measured by the OECD's indicator, are strongly  
42 associated with lower (higher) EOS scores. The correlation coefficient for the panel data is  $-0.68$ .  
43 Furthermore, Figure 2 illustrates that changes in hiring and firing regulation that have occurred in  
44 some countries during our period of investigation are reflected not only in the EPL scores but in the  
45 EOS scores as well. For example, in 1994 Spain relaxed procedural requirements for dismissals for  
46 economic reasons, shortened notice periods, permitted temporary work agencies and tightened rules  
47 governing renewals of fixed-term contracts. As a result, not only did its EPL score drop from 3.8 in  
48 1993 to 3.1 in 1994, in addition Spain's EOS score increased from 2.32 in 1993 to 2.56 in 1994. In  
49 1995, its EOS score increased further to 2.76, which is plausible because the Executive Opinion  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 Surveys are always conducted in the early months of each year. Obviously, in the early months of  
4  
5 1995 the scope of the reform was more clearly visible than in the early months of 1994.  
6  
7

8  
9  
10 Belgium is a similar case in point. In 1997 it reduced restrictions on temporary work agencies and  
11  
12 made fixed-term contracts renewable. As a result, Belgium's EPL score fell from 3.2 in 1996 to 2.2  
13  
14 in 1997. Concurrently, its EOS score increased from 2.63 in 1996 to 3.00 in 1997 and 3.26 in 1998.  
15  
16 The case of New Zealand also illustrates that substantial changes in the strictness of hiring and  
17  
18 firing regulations are reflected in changes in EOS scores. Until 1999, New Zealand's hiring and  
19  
20 firing regulations were relatively flexible. In 2000, the employment relations act tightened  
21  
22 legislation on dismissals, fixed-term contracts and temporary work agencies. This reform is not only  
23  
24 reflected in an increase in New Zealand's EPL score from 0.9 in 1999 to 1.5 in 2000 but also in a  
25  
26 drop of its EOS score from 4.46 in 1999 to 3.00 in 2000 and 2.80 in 2001. The examples of these  
27  
28 three countries illustrate that significant changes in the strictness of hiring and firing regulations are  
29  
30 reflected in corresponding changes in EOS scores.  
31  
32  
33  
34  
35  
36  
37  
38

39 Overall, Figures 1 and 2 indicate a close connection between perceived hiring and firing regulation  
40  
41 and employment protection legislation, as measured by the OECD's indicator. Thus the subjective  
42  
43 data from the Executive Opinion Surveys appear to be well suited for analyzing the impact of hiring  
44  
45 and firing regulations on labor market performance. To be sure, as pointed out previously, they may  
46  
47 have certain limitations. However, objective measures have shortcomings of their own and, on  
48  
49 balance, may be less suitable. For instance, they measure only de jure strictness, whereas the EOS  
50  
51 scores measure de facto strictness, which certainly is more relevant. Thus the judgments of high-  
52  
53 level business executives, as recorded in the Executive Opinion Surveys, provide an alternative  
54  
55 characterization that may shed useful new light on the effects of hiring and firing regulations.  
56  
57 Therefore, this paper complements previous studies of other researchers who have almost  
58  
59 exclusively used objective measures.  
60

1  
2  
3  
4  
5  
6 To measure the performance of the labor market, we use not only the overall rates of unemployment  
7  
8 and employment but also unemployment and employment rates relating to women, youths and the  
9  
10 low skilled. Thus we analyze not only whether the strictness of hiring and firing regulation affects  
11  
12 the general situation on the labor market but also whether it affects three demographic groups that  
13  
14 usually have above-average unemployment rates.  
15  
16

17  
18  
19  
20 We control for the impact of most other labor market institutions that have been considered in the  
21  
22 recent literature. As previous empirical studies have shown, certain labor market institutions appear  
23  
24 to have a considerable impact on the performance of the labor market (see footnote 1). By using  
25  
26 adequate controls, we try to make sure as far as possible that the coefficients on flexible hiring and  
27  
28 firing regulation are not biased due to omitted variables. To date, the OECD has undertaken the  
29  
30 most extensive effort to quantify labor market institutions and has developed the best indicators.  
31  
32 Therefore, we use these data, although they are available for only 19 industrial countries (see  
33  
34 Appendix A). The data cover the following labor market institutions (for variables definitions and  
35  
36 sources, see Appendix B):  
37  
38

- 39 – trade union density,
- 40
- 41 – collective bargaining coverage,
- 42
- 43 – wage bargaining at industry level<sup>6</sup>,
- 44
- 45 – wage bargaining coordination,
- 46
- 47 – tax burden on labor ('tax wedge'),
- 48
- 49 – unemployment benefits replacement rates,
- 50
- 51 – expenditure on active labor market policies per unemployed person.
- 52
- 53
- 54
- 55
- 56
- 57
- 58
- 59
- 60

---

<sup>6</sup> This variable is meant to test Calmfors and Driffill's (1988) hump hypothesis, according to which unemployment (employment) will be comparatively high (low) if wages are negotiated at the industry level.

1  
2  
3 We use the output gap to control for the state of the business cycle. Additionally, we use log income  
4 per capita to account for the effects of differences in the level of economic development, e.g., with  
5 respect to the labor force participation of women. In the regressions to explain the youth  
6 employment rate, we also employ the tertiary enrollment rate. This variable is meant to account for  
7 varying academic education frequencies, which are likely to affect youth employment.  
8  
9

10  
11  
12  
13  
14  
15  
16  
17 Finally, we control for unobserved country effects by using country-specific fixed effects. The fixed  
18 effects regressions, presented in the upper parts of Tables 2 and 3, are the baselines for our  
19 empirical estimates.<sup>7</sup> To check whether other methodologies yield similar results, the lower parts of  
20 both tables present the coefficients on our variable of interest from FGLS regressions with country-  
21 specific random effects and from pooled OLS regressions, respectively. In both cases, the control  
22 variables are the same as the ones used for the fixed effects regressions presented in the upper part  
23 of the tables.<sup>8</sup> We prefer the fixed effects model to the random effects model because in 5 out of 8  
24 regressions, the Hausman test indicates that the random effects estimates may be biased (Tables 2  
25 and 3). We prefer the fixed effects model to the pooled OLS model because, first, the estimates  
26 from the latter model are likely to be biased as well in these five cases, and, second, because the  
27  
28  
29  
30  
31  
32  
33  
34  
35

42  
43  
44  
45

---

46  
47 <sup>7</sup> While controlling for the effects of most other major labor market institutions, the business cycle, the level of  
48 economic development and unobserved country effects goes a long way to avoid omitted variables bias, endogeneity  
49 still may be a problem for estimation because changes in unemployment and employment rates may lead to changes in  
50 the (perceived) strictness of hiring and firing regulation. Unfortunately, due to a lack of instruments we are unable to  
51 directly address this reverse causality problem. (This is in line with the previous literature, which does not use  
52 instruments either.) However, given the results presented in Table 1, it is unlikely that reverse causality is relevant in  
53 our case. (Unemployment and employment rates are strongly correlated with the output gap.)  
54  
55  
56  
57  
58  
59  
60

<sup>8</sup> To save space, the estimates for the controls from the random effects FGLS and the pooled OLS regressions are not presented in Tables 2 and 3.

1  
2  
3 OLS model does not control for unobserved country effects. Instead, it treats successive  
4  
5 observations for each country as independent.<sup>9</sup>  
6  
7  
8  
9

### 10 11 12 13 **3. Results** 14 15 16 17

18 Tables 2 and 3 present our multivariate regressions to explain unemployment and employment  
19 rates, respectively. Our results for the control variables largely accord with those obtained in many  
20 earlier studies. For example, in line with most previous studies we find that an increase in the tax  
21 wedge is likely to both raise unemployment and lower the employment level.<sup>10</sup> Furthermore, we  
22 find that generous unemployment benefit schemes appear to increase unemployment. This is also in  
23 line with most recent studies.<sup>11</sup> Additionally, while some of our estimates corroborate Calmfors and  
24 Driffill's (1988) hump hypothesis, overall the evidence in favor of this hypothesis is weak. This,  
25 too, accords with the previous literature (Aidt and Tzannatos 2002).  
26  
27  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38

39 We now turn to the results for our variable of interest. Indeed, the key finding of our empirical  
40 investigation is that hiring and firing regulation appears to have a statistically significant and robust  
41 effect on labor market performance. The coefficient on flexible hiring and firing regulation is  
42 statistically significant in all fixed effects regressions, in seven out of eight random effects  
43 regressions and in four out of eight pooled OLS regressions. According to our estimates, more  
44 flexible hiring and firing regulation is associated with lower unemployment among the total labor  
45 force as well as among female, young and low-skilled workers (Table 2). Similarly, it is associated  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55

---

56 <sup>9</sup> We also checked the robustness of our results by dropping the control variables from our baseline specifications one at  
57 a time. In these checks (results not reported here), the coefficient on our variable of interest remained very similar.  
58  
59

60 <sup>10</sup> Important studies on the effects of labor taxes include, e.g., Daveri and Tabellini (2000) and Prescott (2004).

<sup>11</sup> See, e.g., Jenkins and Garcia-Serrano (2004), Lalive and Zweimüller (2004) and Nickell et al. (2005).

1  
2  
3 with a higher level of employment among the overall working-age population as well as among  
4  
5 women, youths and the low-skilled (Table 3).<sup>12</sup>  
6  
7  
8  
9

10 Our estimates suggest that liberalizing hiring and firing regulation would have a notable, though  
11 generally modest, pay-off in terms of lower unemployment and higher employment. For example,  
12 according to the Executive Opinion Surveys, France had one of the strictest hiring and firing  
13 regulation in our sample of 19 industrial countries. During the period under review, its EOS score  
14 averaged 2.84. By contrast, Switzerland had one of the most flexible hiring and firing regulation. Its  
15 EOS score averaged 5.31. Switzerland also had substantially lower unemployment rates as well as  
16 substantially higher employment rates, both among the total population and among each of the three  
17 demographic groups. According to our fixed effects estimates, if hiring and firing regulation in  
18 France had been as flexible as in Switzerland, the French unemployment rate would have been 1.1  
19 percentage points lower among the total labor force, 1.6 percentage points lower among women, 2.1  
20 percentage points lower among young people and 1.7 percentage points lower among the low  
21 skilled, *ceteris paribus*. Additionally, France's employment rate would have been 1.1 percentage  
22 points higher both among the total working-age population and among women, 1.5 percentage  
23 points higher among young people and 2.1 percentage points higher among low-skilled workers,  
24 *ceteris paribus*. Of course, these figures should be interpreted with some caution. However, they  
25 illustrate the magnitude of the effects.  
26  
27  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39  
40  
41

43  
44  
45  
46  
47  
48  
49

50 According to our results, flexible hiring and firing regulations are favorable for workers,  
51 particularly for female, young and low-skilled workers. If the regulations relating to fixed-term  
52  
53  
54

---

55  
56 <sup>12</sup> As mentioned in section 1, the evidence from previous empirical studies, which almost exclusively use objective  
57 indicators, so far is mixed. By contrast, our results are less ambiguous. The main reason for this difference may be that  
58 our survey-based indicator is more likely than objective indicators to correctly capture the *de facto* strictness of hiring  
59 and firing regulations and their relevance to the performance of the labor market (see section 2).  
60

1  
2  
3 contracts and temporary work agencies are flexible, these workers seem more often to have an  
4  
5 opportunity to find a job via temporary employment contracts and thus to establish themselves in  
6  
7 working life. If dismissal regulations are not too restrictive, employers seem to be more inclined to  
8  
9 hire women, young people and low-skilled workers for an indefinite period, as they are in a position  
10  
11 to rapidly dismiss them if the profitability of their employment proves to be inadequate or if the  
12  
13 business situation deteriorates. In the end, these workers benefit from this planning scope of  
14  
15 employers.  
16  
17  
18  
19

20  
21  
22 Our results corroborate those theoretical models according to which high costs of hiring and firing  
23  
24 impair the employment situation. For example, extending Bertola's (1990) well-know model,  
25  
26 Risager and Sørensen (1997) have shown that an increase in hiring and firing costs *ceteris paribus*  
27  
28 reduces the return on capital, lowering investment, labor demand and employment. As our results  
29  
30 indicate that strict hiring and firing rules are likely to have an especially adverse impact on women,  
31  
32 young people and low-skilled workers, they particularly corroborate Lindbeck and Snower's (1988)  
33  
34 insider-outsider theory, according to which these kind of rules deteriorate the employment  
35  
36 opportunities of these groups in particular.

#### 46 **4. Conclusion**

47  
48  
49  
50

51 This paper provides new evidence of the effects of hiring and firing regulations on unemployment  
52  
53 and employment rates. In contrast to the previous literature, which almost exclusively relies on hard  
54  
55 data, we use the results of surveys among senior business executives to measure the strictness of  
56  
57 these kind of regulations. The survey data are more likely than objective indicators to correctly  
58  
59 capture their *de facto* strictness and their relevance to the performance of the labor market.  
60  
Controlling for the impact of important labor market institutions, the business cycle, the level of

1  
2  
3 economic development and unobserved country effects, we find that more flexible hiring and firing  
4 regulations are likely to lower unemployment and to increase the employment level. While the  
5 effects on the general population appear to be modest, the effects on women, young people and low-  
6 skilled workers seem to be substantial.

## 34 **Appendix B. Definitions and sources of variables**

35  
36  
37  
38  
39 Active labor market policies: Expenditure on active labor market programs per unemployed person,  
40 divided by 1,000. Source: OECD (2004a).  
41  
42

43  
44 Collective bargaining coverage: Percentage of salaried workers subject to union-negotiated terms  
45 and conditions of employment. Source: OECD (2004a).  
46  
47

48  
49 Employment protection legislation: Indicator for strictness of protection against individual  
50 dismissals and for strictness of regulation of temporary employment (fixed-term contracts,  
51 temporary work agency employment). The indicator ranges from 0 to 6, with higher values  
52 representing stricter regulation. Source: OECD (2004a).  
53  
54  
55

56  
57  
58 Employment rate: Employed aged 15 to 64 years as a percentage of the population in the same age  
59 bracket. Source: International Labour Office (2003), OECD (2005a, 2005b).  
60

1  
2  
3 Employment rate among low-skilled workers: Employed with less than upper secondary education  
4 as a percentage of the population with the same educational attainment. Persons aged 25 to  
5  
6 64 years. Source: OECD (1997, 1998, 1999, 2005a).  
7  
8  
9

10 Female employment rate: Employed women aged 15 to 64 years as a percentage of the female  
11 population in the same age bracket. Source: International Labour Office (2003), OECD  
12 (2005a; 2005b).  
13  
14  
15  
16

17 Female unemployment rate: Unemployed women aged 15 to 64 years as a percentage of the female  
18 labor force in the same age bracket. Source: International Labour Office (2003), OECD  
19 (2005a).  
20  
21  
22  
23

24 Flexible hiring & firing regulation: Survey responses from the World Economic Forum's annual  
25 Executive Opinion Surveys. In each country approximately 60 to 70 senior business  
26 executives were interviewed (see text for a more detailed description of the surveys). The  
27 answer scale ranges from 1 to 7, with higher marks on the scale meaning more flexible  
28 regulation (see Box for phrasing of questions). Source: World Economic Forum (1996,  
29 1997, 1998, 1999, 2000, 2002, 2003), World Economic Forum, Institute for Management  
30 Development (1992, 1993, 1994, 1995).

39  
40

41 Log income per capita: The natural logarithm of gross national income divided by midyear  
42 population, converted into current international dollars using purchasing power parity rates.  
43 Source: World Bank (2005).  
44  
45  
46  
47

48 Output gap: Deviations of actual GDP from potential GDP as a per cent of potential GDP. Source:  
49 OECD (2005c).  
50  
51  
52

53 Tax wedge: Income tax plus employee's and employer's social security contributions less cash  
54 benefits as a percentage of labor costs; one-earner family with two children; average  
55 production worker. Source: OECD (2004b).  
56  
57  
58  
59  
60

1  
2  
3 Tertiary enrollment rate: Students enrolled in tertiary education, regardless of age, as a percentage  
4 of the population of the age group that officially corresponds to this level of education.  
5  
6

7  
8 Source: World Bank (2004).  
9

10 Trade union density: Percentage of employees in trade unions. Source: OECD (2004a).  
11

12 Unemployment benefits replacement rates: Gross unemployment benefits as a percentage of  
13 previous gross wage earnings. Averages across two earnings levels, three family types, and  
14 three unemployment duration categories. Source: OECD (2004c).  
15  
16  
17  
18

19 Unemployment rate: Unemployed as a percentage of the civilian labor force (standardized rates).  
20  
21 Source: OECD (2005c).  
22  
23

24 Unemployment rate among low-skilled workers: Unemployed with less than upper secondary  
25 education as a percentage of the labor force with the same educational attainment. Persons  
26 aged 25 to 64 years. Source: OECD (1997, 1998, 1999, 2005a).

Hausman test			13.05***	

<sup>a)</sup>Data for 19 industrial countries from the years 1992 to 2002. Heteroskedasticity-consistent t-statistics in parentheses (White method), except for the pooled OLS regression, where the figures in parentheses are heteroskedasticity- and autocorrelation-consistent t-statistics (Newey-West method). \*\*\*(\*\*/\*) denotes statistically significant at the 1%(5%/10%) level. All regressions also contain a constant term. See Appendix A for a list of countries. See Appendix B for variables descriptions and sources.

<sup>b)</sup>Swamy-Arora method.

## Figure 1. Hard versus survey data on hiring & firing regulation – Country averages<sup>a)</sup>

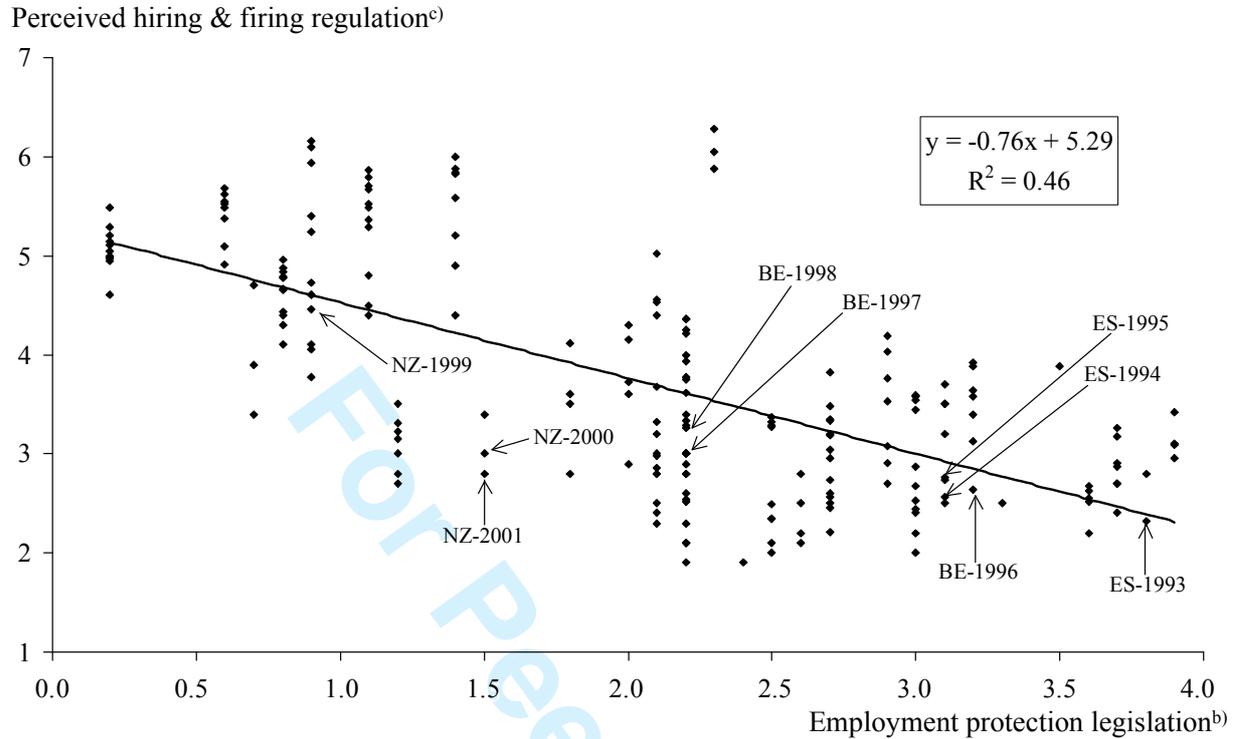

Perceived hiring & firing regulation<sup>c)</sup>

- a) 19 industrial countries; averages over 1992-2002. See Appendix A for a list of countries.
- b) Indicator for strictness of protection against individual dismissals and for strictness of regulation of temporary employment (fixed-term contracts, temporary work agency employment). The indicator ranges from 0 to 6, with higher values representing stricter regulation. It was developed by the OECD.
- c) Answers from the World Economic Forum's Executive Opinion Surveys. The answer scale ranges from 1 to 7, with higher marks on the scale meaning more flexible regulation. See Box for phrasing of questions.

## The Incidence of Mandated Maternity Benefits

By JONATHAN GRUBER\*

*I consider the labor-market effects of mandates which raise the costs of employing a demographically identifiable group. The efficiency of these policies will be largely dependent on the extent to which their costs are shifted to group-specific wages. I study several state and federal mandates which stipulated that childbirth be covered comprehensively in health insurance plans, raising the relative cost of insuring women of childbearing age. I find substantial shifting of the costs of these mandates to the wages of the targeted group. Correspondingly, I find little effect on total labor input for that group. (JEL I18, J32, H51)*

In an era of tight fiscal budget constraints, mandating employer provision of workplace benefits to employees is an attractive means for a government to finance its policy agenda. Consequently, in recent years there has been a growth of interest in mandated benefits as a tool of social policy. For example, the centerpiece of President Bill Clinton's health-care proposal is mandated employer provision of health insurance, and more than 20 states have mandated some form of maternity leave since 1987.

Aside from their political attraction, there may be an efficiency argument for mandates, relative to public expenditure, as a means of financing benefit expansions. As highlighted by Lawrence H. Summers (1989), publicly financed benefits require an increase in government revenue-raising, with the resulting deadweight loss from taxation.

Mandates, however, are financed by a benefits tax; if employees value the benefit that they are receiving, then the deadweight loss from financing that benefit will be lower than from tax financing. In the limit, with full valuation of the benefit by employees, wages will fall to offset the cost of the benefit to the employer, and there will be no efficiency cost. In fact, recent research has suggested that the increased costs of one workplace mandate, workers compensation, were largely shifted to wages with little effect on employment (Jonathan Gruber and Alan B. Krueger, 1991).

This efficiency argument, however, may not apply to a popular type of policy, the "group-specific mandate," which mandates the expansion of benefits for a demographically identifiable group within the workplace.<sup>1</sup> In the case of mandates such as maternity leave, there is likely to be less scope for the free adjustment of wages to

\* Department of Economics, Massachusetts Institute of Technology, Cambridge, MA 02139. I am grateful to Gary Chamberlain, David Cutler, Richard Freeman, Rachel Friedberg, Jerry Hausman, Olivia Mitchell, Rodrigo Vergara, seminar participants at Harvard, MIT, and the NBER, and two anonymous referees for helpful comments; to Josh Angrist, Larry Katz, Jim Poterba, and Larry Summers for both valuable suggestions and guidance; and to the Sloan Foundation and the Harvard Chiles Fellowship for financial support.

<sup>1</sup> Given the prevalence of experience rating in insurance markets, any social insurance mandate may be group-specific, since different individuals may cost the employer different amounts. In this paper, I define group-specific mandates as those which affect a demographically identifiable group only. It is unclear whether the results can be extended to cases in which workers are distinguished along more subtle dimensions.

reflect the valuation of the benefit by the targeted group, since there are barriers to *relative* wage adjustment within the workplace (such as antidiscrimination rules or workplace relative-pay norms) which do not affect the adjustment of overall workplace wage levels. Without the ability of relative wages to adjust, there may be substantial deadweight loss from these mandates even if the benefit is valued by that group. Thus, in considering the efficacy of these mandates, a central consideration is whether the cost of the mandate is shifted to the wages of the group that benefits.

This paper uses a set of “natural experiments” to estimate the response of the labor market to a group-specific mandate: state and federal laws that mandated comprehensive coverage for childbirth in health insurance policies. A commonly accepted feature of health insurance benefits before the mid-1970’s was limited coverage for childbirth. Maternity coverage was sometimes excluded from basic health benefits; if included, it was often subject to flat-rate cash amount limits regardless of the cost of delivery. This differential coverage was widely perceived as discriminatory (Geraldine Leshin, 1981; Alan Guttmacher Institute, 1987). Many states responded to this perception in the 1975–1978 period by passing laws which prohibited treating pregnancy differently from “comparable illnesses” in health insurance benefits. Then, in October 1978, the Federal Government passed the Pregnancy Discrimination Act (PDA), which prohibited any differential treatment of pregnancy in the employment relationship.

This set of laws offers two advantages for studying the labor-market impact of a group-specific mandate. First, they affected a readily identifiable group, women of childbearing age and their husbands (under whose insurance these women may have been covered), so that I am able to study their impact based on observable characteristics. Second, they were fairly costly for these individuals, due both to the widespread existence of differential maternity benefits before 1978 and the large fraction

of health insurance costs for women of childbearing age which are accounted for by maternity benefits.

I use the Current Population Survey (CPS) to study the extent to which the cost of these group-specific mandates was shifted to the targeted group’s wages and the effect on net labor input. I begin by examining changes in wages, hours worked, and employment for married women of childbearing age in states which passed these “maternity mandates,” relative to a set of control individuals within the state and relative to similar states which did not pass this legislation. I then assign each worker an individual-specific cost of the mandate, which is a function of the age-specific cost of maternity coverage, the probability that the worker receives insurance on the job, and the predicted type of insurance coverage that she receives. This allows me to use individual variation in identifying the impact of the mandate and to estimate more precisely the extent of shifting. Finally, I note that, with the passage of the 1978 federal law, the existing state laws provide a natural set of controls; I exploit this “reverse experiment” to confirm my earlier findings. The findings consistently suggest shifting of the costs of the mandates on the order of 100 percent, with little effect on net labor input.

The paper proceeds as follows. Section I presents some background on health insurance benefits for maternity in the 1970’s and discusses the economics of a group-specific mandated benefit. After describing the data and my estimation strategy in Section II, I estimate the impact of the state mandates on the labor-market outcomes of women of childbearing age (and their husbands) in Section III. In Section IV, I study the federal mandate. Section V concludes by discussing the welfare implications of these findings and suggesting directions for future research.

## I. Background

Before 1978, health insurance benefits for maternity were generally limited along two

dimensions: either there was no coverage for pregnancy, or benefits were paid as a flat lump-sum cash amount, regardless of the ultimate costs of childbirth. This stood in contrast to coverage for common illnesses in this era, which was fairly complete.<sup>2</sup> During the 1975–1979 period, 23 states passed laws that outlawed treating pregnancy differently from comparable illnesses. This was also an important feature of the 1978 federal legislation, the PDA, which prohibited discrimination against pregnant women more broadly. The employer cost of the state (and later federal) mandates depends on two factors: the extent of differential coverage before these laws and the cost of its removal.

#### A. *The Extent of Differential Coverage*

There are two previous estimates of the extent of differential coverage for maternity benefits in this era. Dorothy R. Kittner (1978) used a 1976 Labor Department survey of health insurance plans to show that, while over 90 percent of plans included maternity benefits, nearly 60 percent of the plans provided less generous benefits for childbirth than for other disabilities. However, the Health Insurance Association of America (1978) used data from a survey of new group health insurance policies written in early 1978 to estimate that only 52 percent of employees had any coverage for maternity. Both of these estimates are problematic: Kittner's only includes firms with more than 26 employees and does not include information on dependent coverage; the Health Insurance Association of America looks only at new policies, which may have been supplementary to existing policies (and therefore less generous), and does not focus on women of childbearing age.

To obtain more accurate estimates, I use the 1977 National Medical Care Expendi-

<sup>2</sup>This differential coverage may have been a natural response to problems of adverse selection in the timing of pregnancy. Arleen Leibowitz (1990) finds that fertility rates of women with first-dollar coverage were 29-percent higher than those with some coinsurance in the RAND Health Insurance Experiment.

ture Survey (NMCES), which collected data on demographics and health insurance coverage for a nationally representative sample of more than 40,000 individuals. While this survey was completed before the PDA was put in place, many states had passed their own maternity mandates by 1977, so that my calculations will represent underestimates of the extent of discrimination in the early 1970's.<sup>3</sup>

The NMCES contains data on approximately 2,900 females between ages 20 and 40 who were covered through employment-based group health insurance, either in their own name or through a family member. I use "hospital room and board" and "other inpatient services" as comparable illnesses in order to define differential coverage. I find that about 20 percent of women did not have coverage for maternity benefits when they had coverage for either of these comparable illnesses. There were an additional 30 percent of women who received less coverage of the physician's "usual, customary, and reasonable charges" for delivery than for other services, or received only a flat lump-sum provision (less than \$250) for a delivery fee. Thus, at least 50 percent of women faced either differential coverage or benefits.<sup>4</sup>

#### B. *The Cost of Expanding Maternity Benefits*

Estimating the cost of the maternity mandates would require information on the increase in premiums for adding maternity

<sup>3</sup>The data do not contain state identifiers, so I was unable to control for the effects of state laws. Regional controls were not sufficient, due to the widespread passage of state laws in 1976 and 1977. By January 1, 1977, 28 percent of the U.S. population lived in states that had passed mandates; if all firms in these states had completely eradicated differential benefits by the time of the survey, then the discrimination figures should be multiplied by a factor of 1.39.

<sup>4</sup>Another 33 percent of women did not receive any major-medical coverage of normal pregnancies in the presence of major-medical coverage of comparable illnesses. However, it is unclear whether these laws should be construed to require major-medical coverage of normal childbirth.

benefits to a group health package, as well as the cost of increasing the generosity of benefits to the level of comparable illnesses. This sort of data is difficult to gather because nondifferential maternity benefits are now mandated nationally. However, as with all Equal Employment Opportunity Commission legislation, this mandate does not apply to firms with fewer than 15 employees. I have thus been able to gather information on the cost of adding maternity benefits to a small-group plan by using a premium-calculation package from a national insurer. This program is typical of that used by a group-health-insurance salesperson for calculating premiums for a small firm: it inputs the details of the plan and the demographic composition of the workforce and returns the premium cost.<sup>5</sup> For each of several demographic classifications, I use this program to observe the increase in premium cost with the addition of maternity benefits to a typical health insurance plan.

Table 1 presents the cost of adding maternity benefits to a group package for six demographic classifications, in 1990 dollars, in 1978 dollars, and as a percentage of average earnings for each group in 1978. The 1990 cost was deflated to 1978 by using a weighted average of the detailed CPI for hospital services and physician services, where the weights correspond to the fraction of costs in a typical delivery attributable to each.<sup>6</sup> The cost for each group varies widely as a percentage of wages, from less than 1 percent to almost 5 percent. To the extent that there was coverage for childbirth in health insurance plans before the

mandates but differential benefits, the figures in Table 1 will be overestimates of the mandates' costs.<sup>7</sup>

A check on these costs is provided by comparing them to the expected cost of childbirth for an employee in these categories. In 1989, the average cost of a normal delivery was \$4,334 (Health Insurance Association of America, 1989); for married women 20–30 years old, the average probability of having a child in a year was 17.7 percent (U.S. Department of Health and Human Services, 1987). The annual expected cost of childbirth for this group is thus \$767. Compared to the additional cost of \$984 for maternity benefits in family coverage for this age group, this implies an insurance loading factor of 28 percent, which appears reasonable.<sup>8</sup> The high cost of childbirth meant that this mandate was an expensive one for many insured persons.

### C. *The Economics of Group-Specific Mandated Benefits*

The advantages and disadvantages of mandates as tools of social policy are discussed by Thomas G. McGuire and John T. Montgomery (1982), Summers (1989), and Gruber (1992b). Summers presents the efficiency argument for mandates (relative to public provision), noting that when a benefit is provided through the workplace only, individuals will increase their labor supply in order to take advantage of it. Thus, mandates are benefit taxes; if employees value the benefit they are receiving, the increase in labor supply will reduce the deadweight

<sup>5</sup>Since much of the insurance price differential across firm sizes arises from fixed administrative costs, the incremental cost of maternity benefits should not be very sensitive to firm size. The fact that maternity benefits are now mandated nationally for large firms makes this contention difficult to confirm, although, within the range of this program, there is no effect of size differences. My source for this program requested anonymity.

<sup>6</sup>These were two-thirds and one-third, respectively (Health Insurance Association of America, 1989). Unfortunately, the detailed CPI for obstetrics was discontinued in 1978.

<sup>7</sup>These mandates raised the cost of individual workers due to the widespread existence of experience rating in insurance policies in this era (see the appendix to Gruber [1992a]).

<sup>8</sup>Furthermore, the costs in Table 1 will account for the possibility of a nonnormal delivery; in 1989, cesarean sections cost 66-percent more than normal births on average (Health Insurance Association of America, 1989). On the other hand, the fertility rate for working women may be somewhat lower than the average rate overall. A 28-percent loading factor is approximately the average for a firm of 50 employees, according to Congressional Research Service (1988).

TABLE 1—THE COST OF ADDING MATERNITY BENEFITS TO A HEALTH INSURANCE PACKAGE

Coverage	Demographic group	Annual cost (1990 dollars)	Annual cost (1978 dollars)	Cost as percentage of 1978 weekly earnings
Family	20–29-year-old females	\$984	\$360	4.6
Family	30–39-year-old females	\$756	\$277	3.5
Individual	20–29-year-old females	\$324	\$119	1.5
Individual	30–39-year-old females	\$252	\$92	0.9
Family	20–29-year-old males	\$984	\$360	2.9
Family	30–39-year-old males	\$756	\$277	1.7

*Notes:* The source of the data is a premium-calculation program from an anonymous insurance carrier. The cost was calculated for a two-person firm in Maryland. Maryland was a location which was approximately at the midpoint of the locational cost distribution. The results are not sensitive to variations in firm size. Costs are for 1990; they are deflated to 1978 using a weighted average of the detailed CPI for hospital services and physician services, where the weights are  $\frac{2}{3}$  and  $\frac{1}{3}$ , respectively. Costs are normalized by 1978 weekly wages from the May 1978 CPS. For single coverage, wages of unmarried persons are used; for family coverage, wages of married persons are used.

loss of finance. If valuation is full, then there is no deadweight loss from the mandate.

As I showed in an earlier version of this paper (Gruber, 1992a), this analysis is readily extended to the case of a group-specific mandate.<sup>9</sup> However, there may be a number of barriers to full group-specific shifting which are less important when the benefit is extended to everyone in the workplace. Most obviously, there are antidiscrimination regulations which prohibit differential pay for the same job across groups, or which prevent differential promotion decisions by demographic characteristic.<sup>10</sup> Furthermore,

workplace norms that prohibit different pay across groups or union rules about equality of relative pay may have similar effects to antidiscrimination rules. Finally, if the group that benefits is disproportionately composed of workers earning at or near the minimum wage, there may not be scope for shifting to wages.

As Gruber (1992a) shows, these rigidities can cause mandates to have efficiency consequences even in the presence of full valuation, with resulting group-specific unemployment. Furthermore, the distortion will be higher than that which would arise if the group-specific benefit were financed by a payroll tax assessed on all workers. This is because the smaller tax base for a group-specific mandate will lead to a higher tax rate for a given level of expenditures, and the deadweight loss from taxation rises with the square of the tax rate. As Summers (1989 p. 182) states, referring to the effects of these types of impediments, "It is thus possible that mandated benefit programs can work against the interests of those who most

<sup>9</sup>Of course, if there is full valuation, the fact that the benefit is not part of the existing compensation package implies that there must be a market failure in its provision. In fact, there is a strong a priori argument for market failures in many cases of group-specific mandates, such as maternity leave, maternity insurance, or coverage for AIDS, due to problems of adverse selection in insurance markets.

<sup>10</sup>See Ronald G. Ehrenberg and Robert S. Smith (1991) for a discussion of U.S. antidiscrimination legislation, which was in place well before the mid-1970's. In this discussion, I focus only on laws prohibiting discrimination in rates of pay or promotion. In fact, if there are *also* binding restrictions on relative hiring

practices, then employers may be forced to bear the cost of the mandate. If discrimination rules are *only* binding on the hiring side, then they will not impede group-specific shifting in the case of full valuation.

require the benefit being offered. Publicly provided benefits do not drive a wedge between the marginal costs of hiring different workers and so do not give rise to a distortion of this kind.”

Since the efficiency case for mandates rests largely on employee valuation which is reflected in wage adjustments, the empirical work below will estimate the extent of group-specific shifting to wages of the cost of mandated health insurance for maternity. If there is *not* shifting to wages, then either the group that benefits does not value the mandate, or there are impediments to the adjustment of relative wages to reflect that valuation. As a result, there may be large efficiency costs associated with such a policy.

In considering these results, two caveats are in order. First, I am not studying whether mandated maternity benefits represent sensible social policy, but instead only whether there appear to be large efficiency costs from the financing of such policies. In the conclusion, I will consider more broadly the desirability of mandated maternity coverage. Second, I have focused purely on efficiency considerations and have ignored equity considerations about the source of finance of a group-specific mandate. If the goal of a mandate is not to correct a market failure, but rather to provide benefits to some deprived group in society, then full shifting to wages may not be viewed as a desirable outcome. Thus, in considering the results that follow, it is important to understand the goal of government mandate policy: is it to correct a market failure, or to redirect resources across groups?<sup>11</sup>

## II. Data and Identification Strategy

The goal of the empirical work is to identify the effect of laws passed by certain states (experimental states) which affected

particular groups of individuals (treatment group). Identifying this effect requires controlling for any systematic shocks to the labor-market outcomes of the treatment group in the experimental states that are correlated with, but not due to, the law. I do so in three ways in the estimation below. First, I include year effects, to capture any national trends in the earnings of the treatment group. Second, I include state effects, to control for secular earnings differences in the states that passed the laws and those that did not. Finally, I include state-by-year effects, to control for state-specific shocks over this period which are correlated with the passage of these laws. That is, I compare the treatment individuals in the experimental states to a set of control individuals in those same states and measure the change in the treatments' *relative* outcomes, relative to states that did not pass maternity mandates. The identifying assumption of this “differences-in-differences-in-differences” (DDD) estimator are fairly weak: it simply requires that there be no contemporaneous shock that affects the relative outcomes of the treatment group in the same state-years as the law.<sup>12</sup>

The treatment group here comprises those insured workers who are “at risk” for having a child, or whose health insurance covers someone who is at risk for having a child. The controls are other individuals who were directly unaffected by the law. However, the Current Population Survey (before May 1979) contained no information on health insurance coverage. I am thus unable to identify exactly the employees for whom this was a costly mandate.

I address this problem in two ways in the empirical work below. First, I use as the treatment group married women of ages 20–40. This group will contain the individuals for whom the mandate was most costly (according to Table 1), married women of

<sup>11</sup>For the set of laws under study, the answer appears to be the former, as they were part of a larger set of state insurance-market regulations which appeared in the 1970's. See Gruber (1992b) for more detail on these state mandates.

<sup>12</sup>This name derives from the “differences-in-differences” estimator used, for example, by David Card (1990). Such estimation, in my context, would include only state and year effects and would assume that there were no state-specific shocks.

childbearing age. My control group is all individuals over age 40 and single males of ages 20–40. I exclude single 20–40-year-old women, as well as 20–40-year-old married males, who may also be affected by the laws if their insurance covers their wives.<sup>13</sup> This “treatment-dummy” approach has the virtue that it is relatively nonparametric.

Second, I use data on insurance coverage from other data sets to model the likelihood that individuals were covered by insurance and the type of insurance coverage that they receive, and I assign each individual a cost of the mandate based on these predictions and the cost data in Table 1. This approach has the advantage that I use individual variation, rather than differences across broad demographic groups, to identify the impact of the law. However, it has the disadvantage that it imposes strong parametric assumptions. If the functional form for the expected cost of the mandate is incorrect, then the demographic-group dummy may be a more effective means of capturing the law’s impact. Thus, in the empirical work that follows, I will rely on both the treatment-group dummy and the individually parameterized cost measure.

I examine two sets of law changes in order to identify the effect of the maternity mandates. First, I study several of the states that passed the mandates in the mid-1970’s, comparing them to similar states that did not pass mandates. Second, I study the effect of the federal mandate on the states that had not yet passed maternity mandates, using the states that had passed mandates as controls.

I focus on three of the 23 states that passed maternity mandates before the federal PDA: Illinois, New Jersey, and New

York (the “experimental” states). The choice of these three states was motivated by two considerations. First, all of these laws went into effect between July 1, 1976, and January 1, 1977, so that they can be studied simultaneously, and there is sufficient time to examine their impact before the federal law was put into place (October 1978). Second, the data that I use to study the labor-market impact of these laws, the May Current Population Survey, did not identify all states separately before May 1977, but rather grouped some states into regional classifications. Thus, I can only use those states that were identified separately in the survey before 1977.

My set of “nonexperimental” states was chosen using similar criteria: these states had to be separately identified in these CPS’s, and they had to be able to capture any regional shocks to the experimental states. For Illinois, the control states used are Ohio and Indiana; for New Jersey and New York, the controls are Connecticut, Massachusetts, and North Carolina.<sup>14</sup>

The data consist of observations on all individuals in these sets of experimental and nonexperimental locations for two years before the legislation (1974 and 1975) and for two years after the legislation (1977 and 1978). Because I use the May CPS, the 1978 survey collects data from before the passage of the federal law. The means of the data are presented in the left-hand panel of Table 2, for the experimental states and the nonexperimentals (both for the “before” years and for the “after” years), for all wage-earners.<sup>15</sup>

<sup>13</sup>That is, there are three demographic subsets of costly individuals under the mandate, and the treatment-dummy approach focuses on just one (married women). Approximately 56 percent of working married women had insurance from their employers in 1979; as I will show below, the expected cost of the mandate is roughly comparable across these three groups, as a fraction of wages. I therefore focus on married women for expositional ease; the effects on the other groups, as well as the overall treatment effect, is presented below.

<sup>14</sup>Pennsylvania could not be used as a “mid-Atlantic” control because it implemented broad anti-sex-discrimination insurance regulations during 1977, which included a “maternity mandate.” North Carolina is included as a control in order to avoid comparing New York and New Jersey solely to New England; the results are similar if North Carolina is excluded.

<sup>15</sup>Hourly wages are in 1978 dollars. I exclude any individuals who report earning less than \$1/hour or more than \$100/hour in 1978 dollars. I also exclude any persons less than 20 years old or older than 65, and I likewise exclude the self-employed. The means are unweighted.

TABLE 2—MEANS FOR ALL WAGE-EARNERS

Variable	State laws				Federal PDA			
	Nonexperimental states		Experimental states		Nonexperimental states		Experimental states	
	Before law	After law	Before law	After law	Before law	After law	Before law	After law
Percentage female	41.4 [49.3]	43.9 [49.6]	41.4 [49.3]	43.1 [49.5]	44.4 [49.7]	45.6 [49.8]	44.5 [49.7]	45.8 [49.8]
Average age	38.1 [12.6]	37.6 [12.5]	38.9 [12.6]	38.4 [12.6]	37.6 [12.7]	37.5 [12.4]	37.5 [12.7]	37.2 [12.4]
Percentage married	75.0 [43.3]	70.8 [45.5]	71.6 [45.1]	67.9 [46.7]	65.7 [47.5]	63.8 [48.1]	70.0 [45.8]	67.0 [47.0]
Percentage nonwhite	8.8 [28.3]	9.2 [28.9]	10.2 [30.3]	12.0 [32.5]	12.3 [32.8]	13.5 [34.2]	10.9 [31.2]	11.2 [31.4]
Average education	12.1 [2.87]	12.3 [2.81]	12.4 [2.94]	12.7 [2.88]	12.5 [3.04]	12.7 [2.99]	12.3 [2.97]	12.6 [2.88]
Average hourly wage	5.68 [3.31]	5.59 [3.16]	6.61 [3.98]	6.40 [3.62]	6.33 [4.02]	5.88 [3.74]	5.80 [3.81]	5.49 [3.63]
Percentage union	27.0 [44.4]	26.8 [44.3]	33.4 [47.2]	33.8 [47.3]				
Percentage manufacturing	36.5 [48.2]	35.3 [47.8]	28.5 [45.1]	26.6 [44.2]	25.1 [43.3]	23.9 [42.6]	23.6 [42.5]	22.6 [41.8]
Percentage services	29.7 [47.2]	31.5 [46.5]	35.3 [47.8]	37.3 [48.4]	41.4 [49.3]	42.6 [49.4]	39.9 [49.0]	40.9 [49.2]
Weekly cost of mandate	4.01 [1.68]	3.87 [1.65]	3.92 [1.66]	3.85 [1.63]	3.64 [1.59]	3.56 [1.58]	3.71 [1.60]	3.64 [1.59]
Cost/wages	0.020 [0.010]	0.020 [0.010]	0.018 [0.009]	0.018 [0.010]	0.019 [0.012]	0.021 [0.013]	0.021 [0.013]	0.022 [0.013]
N:	9,954	10,180	10,597	10,636	41,772	45,332	48,713	59,647

Notes: Numbers in square brackets are standard deviations. Observations with wages below \$1/hour or above \$100/hour are dropped, as are individuals younger than 20 or older than 65 and the self-employed. See text for definitions of experimental and nonexperimental states and for definitions of before and after years.

There are not many striking differences across the groups of states: the experimental states have higher wages, are more unionized, and are less manufacturing-oriented. Differences in unionization and industry distribution, as well as systematic wage differences across locations, are controlled for in the estimation. Overall, wages fell more in the experimental states than in the nonexperimental states; below, I will assess whether the maternity mandates played any role in this relative fall.

The federal legislation provides a distinct opportunity to study the impacts of increasing the costs of health insurance coverage for maternity. In this case, the states that had already passed maternity mandates are

the nonexperimentals, and those that had not are the experimentals. The advantage of this “experiment” is that by this later date the CPS was identifying all states separately, so that I am able to use as control states all those states that had passed laws by January 1, 1977 (12 states), and as experimentals all states that did not pass laws before 1979 (28 states).<sup>16</sup> These states are more broadly representative of the country

<sup>16</sup>The controls are Arkansas, California, Colorado, Hawaii, Idaho, Illinois, Iowa, Maryland, New Jersey, New York, Tennessee, and Wisconsin. The experimen-

as a whole, which should help to overcome any problems induced by using three (somewhat similar) states as experimentals in the earlier estimation. The disadvantage is that the PDA was more expansive than the state mandates, covering the entire employment relationship, rather than just health benefits. Thus, there may have been some effect on the cost of employing women of child-bearing age in the nonexperimental states as well.<sup>17</sup> Nevertheless, health-insurance industry representatives estimated that the effects on health benefit plans would represent two-thirds of the cost of implementing the PDA (Commerce Clearing House, 1978). To the extent that the net cost difference across these two sets of states represents the health insurance requirements of the law only, the shifting estimates should be comparable to those from the first (state mandates) strategy.

I use the 1978 and 1979 (before), and 1981 and 1982 (after) March CPS to study the impact of the federal law. The March data differ from the May data used earlier in that the earnings and labor-market data are retrospective; that is, individuals are asked for their annual earnings, weeks worked, and usual hours per week in the previous year.<sup>18</sup> The means for the federal law change are presented in the right-hand panel of Table 2. Once again, the two sets

of states are fairly similar: in this case, the experimental states have slightly lower wages and are less manufacturing-oriented.

### III. The Labor-Market Impact of the State Laws

#### A. DDD Estimation

Table 3 illustrates DDD estimation of the effect of the maternity mandates on wages. The top panel compares the change in wages for 20–40-year-old married women in the states that passed the laws to the change for 20–40-year-old married women in the nonexperimental states. Each cell contains the mean average real wage for the group labeled on the axes, along with the standard error and the number of observations. There was a 3.4-percent fall in the real wages of women in the experimental states over this period, compared to a 2.8-percent rise in the real wages of women in other states. Thus, there was a (significant) 6.2-percent relative fall in the wages of women of child-bearing age in states that passed these laws; this is the differences-in-differences estimate of the law's impact. This figure seems somewhat large given the magnitude of the costs identified in Table 1.

However, if there was a distinct labor-market shock to the experimental states over this period, this estimate does not identify the impact of the law. I examine this in the bottom panel of Table 3, where I perform the same exercise for the control group, all those older than 40 and single males ages 20–40. For that group, I do find a fall in wages in the experimental states, relative to the other states, of 0.8 percent. Although not significant, this suggests that it may be important to control for state-specific shocks in estimating the impact of the law.

Taking the difference between the two panels of Table 3, there is a 5.4-percent fall in the *relative* wages of 20–40-year-old married women in the states that passed the laws, compared to the change in relative wages in the nonexperimental states. This statistically significant DDD estimate provides some evidence that the cost of a group-specific mandate is borne by

---

tals are Alabama, Alaska, Delaware, the District of Columbia, Indiana, Kentucky, Louisiana, Maine, Massachusetts, Mississippi, Missouri, Montana, Nebraska, New Hampshire, New Mexico, North Carolina, North Dakota, Ohio, Oklahoma, Rhode Island, South Carolina, South Dakota, Texas, Utah, Vermont, Washington, West Virginia, and Wyoming. Connecticut was excluded in this part of the study because the state mandated benefit nondiscrimination rules for all groups in 1979.

<sup>17</sup>For example, another major cost of the PDA was the requirement that firms offering disability coverage extend that coverage to include pregnancy.

<sup>18</sup>Thus, the actual labor-market data come from 1977, 1978, 1980, and 1981. The use of the March CPS was dictated by the fact that, starting in 1979, the May CPS only asked earnings information of one-quarter of the sample. The March CPS also does not report data on union status.

members of that group. However, its interpretation is problematic, since there may be important variation in the effect of the law within the set of married 20–40-year-old women; for example, only some of these women will have insurance on the job. This source of variation will be exploited below, where I build individual-specific measures of the impact of the law. First, however, I discuss how the analysis of Table 3 can be expressed within a regression framework.

### B. Regression Framework for DDD Estimation

The sampling variance of the DDD estimate in Table 3 can be reduced by moving to a regression framework, which allows me to control for other observables that affect the outcome variables of interest. The regression equation has the following form:

$$(1) \quad W_{ijt} = \alpha + \beta_1 X_{ijt} + \beta_2 \tau_t + \beta_3 \delta_j \\ + \beta_4 \text{TREAT}_i + \beta_5 (\delta_j \times \tau_t) \\ + \beta_6 (\tau_t \times \text{TREAT}_i) \\ + \beta_7 (\delta_j \times \text{TREAT}_i) \\ + \beta_8 (\delta_j \times \tau_t \times \text{TREAT}_i).$$

In this equation,  $i$  indexes individuals,  $j$  indexes states (1 if experimental state, 0 if nonexperimental), and  $t$  indexes years (1 if after the law, 0 if before).  $W$  is the log real hourly wage,  $X$  is a vector of observable characteristics,  $\delta_j$  is a fixed state effect,  $\tau_t$  is a fixed year effect, and  $\text{TREAT}$  is a dummy for treatment group (1 if treatment, 0 if control).

The analogy of this regression to Table 3 is straightforward. The fixed effects control for the time-series changes in wages ( $\beta_2$ ), the time-invariant characteristics of the experimental states ( $\beta_3$ ), and the time-invariant characteristics of the treatment group ( $\beta_4$ ). The second-level interactions control for changes over time in the experimental states ( $\beta_5$ ), changes over time for the treatment group nationwide ( $\beta_6$ ), and time-invariant characteristics of the treatment group in the experimental states ( $\beta_7$ ). The third-level interaction ( $\beta_8$ ) captures all

variation in wages specific to the treatments (relative to controls) in the experimental states (relative to the nonexperimentals) in the years after the law (relative to before the law). This is the DDD estimate of the extent of shifting of the cost of the mandate to group-specific wages. The set of demographic covariates used includes education, experience and its square, sex, marital status, a marital-status  $\times$  sex interaction, a dummy for nonwhite, a dummy for union status, dummies for 15 major industries, and separate year dummies for 1974 and 1978.

The first row of Table 4 presents the estimates of the third-level interaction from (1),  $\beta_8$ . The coefficient indicates that wages fell by 4.3 percent for the treatment group; it is marginally statistically significant. While this is slightly smaller than the estimate from Table 3, the standard error has been reduced as well, so that the significance is approximately the same. The fact that introducing the other covariates did not have a sizeable impact on this coefficient is comforting, given the experimental interpretation of the estimate.<sup>19</sup>

The next two columns of Table 4 examine the effects of this mandate on hours of work and probability of employment. If this benefit is fully valued, on average, by workers in the treatment group, there should be no change in their net labor input. However, even with full valuation on average, it is possible that the mandate could affect the *composition* of labor input. This mandate represents an increase in the fixed costs of employment and is thus more costly (as a

<sup>19</sup>The other coefficients in the regression are of their expected signs and magnitudes. There is a 1.2-percent fall in wages for the within-state control group. This suggests that the experimental states, on average, saw a negative shock over this period. Alternatively, the mandate itself could be causing this fall for the control group, if the groups are complements or if there is cross-subsidization across groups due to relative pay restrictions. However, given the findings of substantial shifting to group-specific wages, such spillover seems unlikely. The full set of coefficients are reported in Gruber (1992a).

TABLE 3—DDD ESTIMATES OF THE IMPACT OF STATE MANDATES ON HOURLY WAGES

Location/year	Before law change	After law change	Time difference for location
<i>A. Treatment Individuals: Married Women, 20–40 Years Old:</i>			
Experimental states	1.547 (0.012) [1,400]	1.513 (0.012) [1,496]	–0.034 (0.017)
Nonexperimental states	1.369 (0.010) [1,480]	1.397 (0.010) [1,640]	0.028 (0.014)
Location difference at a point in time:	0.178 (0.016)	0.116 (0.015)	
Difference-in-difference:	–0.062 (0.022)		
<i>B. Control Group: Over 40 and Single Males 20–40:</i>			
Experimental states	1.759 (0.007) [5,624]	1.748 (0.007) [5,407]	–0.011 (0.010)
Nonexperimental states	1.630 (0.007) [4,959]	1.627 (0.007) [4,928]	–0.003 (0.010)
Location difference at a point in time:	0.129 (0.010)	0.121 (0.010)	
Difference-in-difference:	–0.008: (0.014)		
<b>DDD:</b>	<b>–0.054</b> <b>(0.026)</b>		

*Notes:* Cells contain mean log hourly wage for the group identified. Standard errors are given in parentheses; sample sizes are given in square brackets. Years before/after law change, and experimental/nonexperimental states, are defined in the text. Difference-in-difference-in-difference (DDD) is the difference-in-difference from the upper panel minus that in the lower panel.

fraction of labor payments) for low-hours employees. If employers are able to lower each worker's wages by the lump-sum cost of the mandate, then neither hours nor employment should change. However, if employers are not able to implement a percentage reduction in pay that is inversely proportional to hours worked, then part-time workers will become more expensive. Employers may thus react by increasing hours and lowering employment, reducing

the cost per hour of the mandate while leaving total labor input unchanged.

Of course, if the wage offset is lower for low-hours workers, workers will demand the opposite outcome; there will be increasing demand for part-time work, with hours falling and employment increasing. Furthermore, since part-time workers may be more readily excluded from health insurance coverage, there may also be a countervailing effect on the employer side, as full-time

TABLE 4—TREATMENT-DUMMY RESULTS ACROSS DEMOGRAPHIC GROUPS

Group	Log hourly wage	Log hours/week	Employment (probit)	Percentage changes in labor input
Married women, ages 20–40	–0.043 (0.023)	0.049 (0.022)	–0.047 (0.048) [–0.016]	1.40
Single women, ages 20–40	–0.042 (0.026)	–0.014 (0.024)	–0.095 (0.064) [–0.030]	–5.95
Married men, ages 20–40	–0.009 (0.018)	0.030 (0.015)	–0.139 (0.072) [–0.038]	–1.08
All treatments	–0.023 (0.015)	0.027 (0.014)	–0.079 (0.039) [–0.024]	–0.88

*Notes:* Standard errors are given in parentheses. The coefficient is that on the third-level interaction in equation (1). The treatment group is the group indicated for each row. The control group is the same as that for Table 3 (all those older than 40 and single men younger than 40). The number in brackets in the employment column is the marginal probability (see text). The change in total labor input is the change in hours at the average-employment/population ratio plus the change in employment in terms of average hours per employed person. This is then divided by the ratio of employment to population to get per-worker figures and then divided by average hours per week for the treatment group to get a percentage change.

employees are replaced with their (uninsured) part-time counterparts. In this case as well, hours would fall, and employment would rise.<sup>20</sup> Thus, the effects on hours and employment are uncertain, even if the cost of the mandate can be shifted to wages on average.

Table 4 confirms the conclusion of full shifting, on average, but does show some compositional changes. In the second column, the dependent variable is the log of weekly hours of work; hours rise by a significant 4.9 percent for the treatment group. I measure employment by a dummy variable which equals 1 if the individual is employed, and 0 otherwise (unemployed or out of the labor force); the employment regressions are run as probits. Table 4 also shows an insignificant fall in employment; it implies that the treatments saw a 1.6-percent fall in employment over this period, relative to the

sets of controls.<sup>21</sup> There is a small net positive effect on total labor input of 0.48 hours per week per worker; this amounts to a rise in hours of about 1.4 percent of average hours per week for the treatment group.<sup>22</sup> This is consistent with the large wage offsets uncovered in the columns for log hourly wage and log hours/week.

As mentioned above, married women represent only one of three groups of workers that are potentially affected by these mandates. The costs of employing single women of childbearing age rose as well, as did costs

<sup>21</sup>This is calculated by using the probit coefficients to predict the probability of employment as if all individuals in the experimental state/years were treatments, then predicting the probability as if none were treatments, and taking the average of the differences of these predictions across individuals.

<sup>22</sup>I calculate the change in total labor input as the change in hours at the average employment-to-population ratio plus the change in employment at average hours per employed person. This is then divided by the employment-to-population ratio to get per-worker figures.

<sup>20</sup>Of course, another option for employers is to drop insurance coverage altogether. Gruber (1992b) finds that there was little effect of other expensive state-mandated benefits on the propensity of firms to offer health insurance.

of employing married males, who may cover their wives in their insurance policies. The effects on these other groups, as well as the effect on all of these groups together, are presented in the remaining rows of Table 4. There are some differences in the results across groups: shifting to wages is small and insignificant for married males, and there is evidence of a sizable fall in total labor input for single females, which is of the same magnitude as the fall in wages for that group. However, the overall results across all groups (i.e., from a regression in which the treatment dummy is 1 for members of all of these groups) is consistent with that for married women only: a decrease in wages, a rise in hours, and a fall in employment, with an overall labor input effect that is small relative to the wage effect.

The reasons for this differential effect across the demographic subgroups may be heterogeneity in the impact of this law across the groups, due to differential probabilities of insurance coverage and costs of extending maternity health-insurance benefits. In the next subsection, I address this heterogeneity by attempting to model the individual-specific cost of these mandates.<sup>23</sup>

### C. Individual Parameterization of the Cost of the Mandates

In assessing the cost of these maternity mandates for each individual, one must consider (i) whether the individual is covered by insurance and whether that insurance provides differential maternity benefits; (ii)

whether this coverage is from the individual's own job or is through a family member; (iii) whether the coverage is for the entire family, or just the individual;<sup>24</sup> and (iv) the individual's (or spouse's) age-specific probability of childbearing. Unfortunately, the CPS does not contain information about insurance coverage during the 1974–1978 period. I have thus calculated *predicted* individual-specific costs, drawing on three sources of data: the estimates of age-specific costs from the premium program; data on the probability of insurance coverage in the 1979 May CPS Pension Supplement; and data on type of insurance coverage from the 1977 NMCES. These cost calculations are described in detail in the appendix to Gruber (1992a); I will briefly review them here.

For all individuals over age 40, and for single males ages 20–40, a cost of zero is assigned. I divide the remaining 20–40-year-olds into three treatment groups: single females, married females, and married males. I use the CPS Pension Supplement, which collects data on employer-provided insurance, to model the probability of insurance coverage as a function of individual demographics, hours of work, union status, and industry of employment. Separate predictor regressions are run for each of the three groups. I then create an extract from the NMCES of all persons in each of these three groups who are employed, who have insurance on the job, and who are the primary insured for their household. For each group I model the probability that a worker will have family coverage versus individual coverage as a function of demographics, industry, spouse's employment status, and spouse's industry.

<sup>23</sup>As I discuss in the next subsection, the expected costs of the mandates across the three groups are roughly equal. The reason for the much smaller wage effect for married males is therefore unclear; it may be that employers perceived the law as having a larger effect on the cost of employing women for other reasons. In any case, the coefficients across the different groups are not significantly different from each other, and the more appropriate test of the effect of the laws is to use the variation in the cost across individuals, which I do next. The overall conclusions from the individually parameterized results below are not sensitive to the exclusion of any one of these three groups from the analysis.

<sup>24</sup>The premium-pricing program described earlier assigns a much higher incremental cost of adding maternity benefits to family coverage than to individual coverage. Presumably, this proxies for differences in the probability of childbearing. Indeed, the relative cost difference between the two types of policies is almost exactly the same as the difference in the relative probabilities of childbearing between single and married women (U.S. Department of Health and Human Services, 1987).

Finally, I use Table 1 to assign age-specific costs: I take a weighted average of the costs of individual and family coverage (where the weights are the predicted probabilities of each type of coverage from the NMCES) and multiply by the predicted probability of having insurance coverage on the job. This yields a predicted weekly cost which varies by the six 10-year age groupings in Table 1.<sup>25</sup> The results of this exercise, for all treatment individuals, are presented at the bottom of Table 2. The cost averages \$3.91 per week, which is 1.9 percent of wages on average; it has a maximum value of 28 percent of wages. The average cost is not appreciably different across the experimental/nonexperimental locations, nor does it change much over time. The weekly cost is highest for married males, reflecting both the high cost for that group from Table 1 and the fact that they are more likely than married females to be the primary insured. However, once costs are normalized by wages, they are roughly equal for married men and women, and slightly lower for single women.

Since a fixed-cost-of-employment mandate is more costly for part-time workers, the predicted cost should also be normalized by hours worked per week, given that the probability of insurance coverage has been appropriately downweighted for that group in the predictor equation. However, for workers who report weekly wages in the CPS, the hourly wage is calculated as the weekly wage divided by hours worked. Thus, if there is measurement error in hours, this may induce a spurious correlation between

hourly wage and hourly mandate cost. I will present results below both with and without the normalization for hours worked, as the results are sensitive to the specification chosen.

The individually parameterized cost measure can be introduced in place of the treatment dummy in equation (4). Since the calculated cost of the mandate is expressed in dollars, it would be interpreted most straightforwardly in a levels wage equation, rather than the log wage specification used earlier. However, since wages are distributed lognormally, a levels wage equation is potentially misspecified. In a log wage equation, the linear cost measure estimates the percentage fall in wages for a one-dollar increase in cost, which varies along the wage distribution. Ideally, this problem could be solved by normalizing costs by individual wages, but this would induce a spurious negative correlation between the dependent and independent variables in the wage regression. Instead, I note that the wage equation can be specified as  $W = (e^{\beta X} + \text{COSTNN})e^{\varepsilon}$ , where COSTNN is the individual hourly mandate cost, and  $\varepsilon$  is a normally distributed error term. Taking logs of both sides of this equation, one obtains:  $\log(W) = \log(e^{\beta X} + \text{COSTNN}) + \varepsilon$ . This nonlinear model thus has both a normally distributed error and a directly interpretable coefficient on the individual mandate cost in dollars.<sup>26</sup>

To the extent that my estimate of the cost of the mandate is correct, a coefficient of  $-1$  on the third-level interaction would in-

<sup>25</sup>In an earlier version of this paper, I also let the cost vary by single-year age-specific probabilities of childbearing. The results were similar; I rely on the 10-year averages because this seems to be the level at which the costs of insurance vary. For married males, I use own age rather than wife's age, since this appears to be the relevant variable for the premium calculation. Ideally, I would also control for the probability that the individual has differential benefit coverage; however, I am not confident enough in my estimates of the incidence of differential benefits to make this an integral part of the analysis. This implies that the result may underestimate the extent of shifting.

<sup>26</sup>The results are quite similar when the cost is included linearly in the log wage regression and normalized by average wages (see Gruber, 1992a). I have also tried entering hourly cost, not normalized by wages, into a linear wage equation: the estimated third-level interaction is  $-3.76$ , with a standard error of  $0.99$ . Furthermore, the coefficient on cost (not normalized by wages) in a log wage regression should fall as the wage rises, since a dollar cost increase represents a smaller percentage of wages. This prediction is testable by cutting the sample by some measure of *permanent* income, such as education. In fact, the shifting coefficient for workers who did not graduate from high school is twice that of those who did, although the estimates are not significantly different from each other.

TABLE 5—WAGES AND LABOR INPUT RESULTS—PARAMETRIZED COST OF THE MANDATE

Coefficient	Specification				
	(i) Log wage	(ii) Log wage (no hours)	(iii) Log wage (full-time)	(iv) Log hours/week	(v) Employment (probit)
$\beta_8$	-2.140 (0.759)	-0.028 (0.019)	-0.037 (0.019)	0.0049 (0.0031)	-0.027 (0.011) [-0.022]
Shifting (percentage):	214	109	156		
N:	41,367	41,367	35,868	41,367	84,305

Notes: All regressions are estimated by nonlinear least squares, as described in the text. Standard errors are given in parentheses. The mandate cost in columns (ii) and (iii) is not normalized by hours worked; shifting is calculated at average hours for the treatments. The sample in column (iii) is restricted to those who work at least 35 hours per week. Column (v) is a probit. Cost is assigned by demographic group average. The number in brackets shows the change in the probability of employment for a \$1 increase in costs.

dicate full shifting to wages. Even if the level of the estimate is incorrect, however, so long as I capture the *relative costliness* across individuals appropriately, I will gain efficiency in estimation over the treatment-dummy case by using individual variation in relative costs.<sup>27</sup>

#### D. Individual Parameterization: Results

Table 5 presents the coefficient of interest from wage regressions with the individually parameterized costs. In column (i), the cost is normalized by hours worked. The regression indicates very sizable shifting to wages, on the order of 210 percent of the cost of the mandate. While this coefficient is significantly different from 0, it is not significantly different from 1, which would imply full shifting to wages.

In column (ii), I remove the normalization of the mandate cost for hours worked. At the mean hours worked for the treat-

ment group, there is 109 percent shifting to wages, but the estimate is not significant. This reduction in the shifting coefficient implies that the fall in wages was greater for the low-hours workers, since they saw the greatest increase in predicted costs when predicted costs were normalized by hours worked. To the extent that these part-time workers were covered by health insurance, this is a sensible finding, since the hourly cost of the mandate was highest for them. However, only 20 percent of individuals who worked less than 35 hours per week in 1979 were covered by health insurance (based on tabulations from the May 1979 CPS). The predictor equation for the probability of insurance coverage controls for hours worked, a dummy for part-time work, and interactions of union status with hours of work and the part-time dummy; nevertheless, it would be disturbing if these results were driven solely by low-hours workers.

Thus, in column (iii) of Table 5, I focus only on full-time workers (35 hours per week or more); over 75 percent of this group is covered by insurance on the job. Cost is not normalized by hours worked for full-time workers, since the noise-to-signal ratio in hours is presumably quite high for this group.<sup>28</sup> The results reveal that the conclu-

<sup>27</sup>Using this estimated cost in place of a demographic dummy does introduce more imprecision into the estimation, since I have predicted the cost from earlier regression models. This imprecision will not be appropriately reflected in the standard errors in my outcome regressions, which will therefore be too small. However, this problem can be shown to disappear as the precision of the predictor equations increases; the predictor equations used fit fairly well, predicting between 73 percent and 85 percent of the cases correctly.

<sup>28</sup>The shifting estimate is similar if cost is normalized.

sion of group-specific shifting was not driven by low-hours workers. The shifting estimate for full-time workers lies between the estimates of columns (i) and (ii).

If these estimates are correct, and there is full shifting of the cost of this mandate to the wages of the treatment group, then there should be no net effect on labor input. I test this in columns (iv) and (v) of Table 5. In column (iv), the dependent variable is the log of hours worked, and the cost is not normalized by average wages or hours.<sup>29</sup> The regression reveals a rise in hours worked by about 0.5 percent of their average level for a \$1 increase in cost.

For the cost measure in the employment regression, I cannot predict individual probabilities of insurance coverage or type of coverage, since I cannot measure industry of employment or hours worked for the unemployed. I thus assign each individual the average probability of insurance coverage and the average probability of family/individual coverage for his or her demographic group (single females, married females, and married males). That is, I assume that if nonemployed individuals were employed, they would face the same probabilities of insurance coverage and buy the same type of insurance as their demographic counterparts who are employed. As before, the employment regression is run as a probit.

As column (v) of Table 5 shows, there is a significant fall in employment for the treatment group. The probit coefficient implies that a \$1 increase in cost would lead to a 0.22-percent fall in probability of employment.<sup>30</sup> Taken together with the hours co-

efficient, this implies a rise in total labor input per worker of 0.63 percent of its average value for a 100-percent rise in cost. This can be contrasted to the estimate of a fall in wages of 4.7 percent of their average value. Thus, the estimated effect on net labor input is small, which confirms the conclusion of substantial shifting to wages.<sup>31</sup>

#### IV. The Federal Experiment

Tables 4 and 5 find extensive shifting of the cost of the maternity mandates to group-specific wages, both in a relatively unrestricted treatment-group-dummy model and in a more parametric specification which tried to capture individual variation in the cost of the mandates. However, these results emerged from the analysis of only three experiments, using a select set of control states. This suggests the desirability of finding an example of a group-specific mandate that affected a broader range of states. The federal PDA of 1978 provides such an example.

The federal law can be studied within the same regression framework used above, with the exceptions that there are no data on union status and that the year dummies are now for 1978 and 1981. These results

---

in predicted probability of employment across treatment individuals gives the effects of a dollar increase in costs.

<sup>31</sup>I have also performed two specification checks to assess the robustness of this result. First, I assessed whether one of the law changes was driving the results, by running the regression separately by state, relative to the regional controls. While I found stronger results for New York and weaker results for New Jersey, the result was not driven by any one state's experience; the shifting estimate was significant at the 10-percent level even if New York was excluded. In all cases the net labor-input effect was very small relative to the wage effect, confirming the conclusion of full shifting. Second, in an attempt to include more detailed controls for industry-specific shocks which may be driving the results, I allowed the industry dummies to vary by state and year. This is a very general specification, which allows for state-specific, year-specific, and state  $\times$  year-specific shocks by industry. Nevertheless, the shifting estimate is virtually identical to that in column (i) of Table 5. These results are reported in Gruber (1992a).

<sup>29</sup>While normalizing by hours is once again theoretically appropriate, it would induce a spurious negative correlation between predicted cost and hours worked. Furthermore, the predictor equation for the probability of insurance coverage used here does not control for hours worked, since this would induce a spurious positive correlation.

<sup>30</sup>This is calculated similarly to the earlier case: predicted employment is calculated at average cost and at average cost plus one dollar for the treatment group in the experimental state/years; the average difference

TABLE 6—FURTHER RESULTS—FEDERAL EXPERIMENT

Demographic group/treatment	Specification					
	(i) Log wage	(ii) Log wage (no hours)	(iii) Log wage (full-time)	(iv) Log hours/week	(v) Employment (probit)	(vi) Change in total labor input

Married men, ages 20–40	–0.008 (0.0012)			–0.0008 (0.0073)	0.0020 (0.0046) [0.0005]	–0.0003
All treatments	–0.0014 (0.0009)			0.0032 (0.0064)	0.0001 (0.0233) [0.00004]	0.0033
Individual parameterization	–0.587 (0.412)	–0.023 (0.010)	–0.017 (0.010)	–0.0002 (0.0015)	0.0007 (0.0068) [0.00005]	–0.0005
Shifting (percentage):	59	90	75			

Notes: The coefficient is  $\beta_8$  in equation (1). Standard errors are given in parentheses. In column (v), the number in brackets interprets the probit coefficient for employment, by calculating the change in probability of employment for a \$1 increase in the cost of the mandate. Change in total labor input is the change in total hours per week per worker for a 100-percent rise in the cost of the mandate. It is calculated by adding the change in hours at average employment to the change in employment at average hours, for a \$1 rise in cost, for the relevant treatment group. This is then divided by average labor input (hours times employment/population ratio) for the treatment group (and multiplied by cost per week in the parameterized cost case) to get the percentage change in labor input for a 100-percent rise in the dollar cost.

are reported in Table 6. The first row repeats the estimation using the demographic dummy, which is once again equal to 1 for married women aged 20–40, and 0 for all others (excluding married 20–40-year-old males and single 20–40-year-old women). There is evidence of shifting to wages, although the magnitude is approximately half that of the earlier regressions and is only significant at the 10-percent level. There is also an increase in hours and a fall in employment, as before, although neither the hours nor the employment coefficient is as large as the respective standard errors. The net effect on labor input is approximately zero. Thus, once again one finds a fall in group-specific wages with no effect on net labor input.

The next three rows of Table 6 examine the other demographic groups. The wage results for both single women and married men are weaker than those for married

women, although in no case are the estimates significantly different from each other. The overall treatment effect is about two-thirds the size of the effect for married women only. The labor-input results are once again mixed; overall, there is a small rise in hours and no effect on employment.

As above, moving to the individually parameterized cost yields further variation which can be used to pin down the extent of shifting to wages more precisely. The individually parameterized cost is calculated in the same way as for the state laws, and this is presented at the bottom of the right-hand side panel of Table 2.<sup>32</sup> The results are quite similar to those from the state laws,

<sup>32</sup>The only difference is that the predictor equations now no longer include controls for union status and its interaction with hours worked and part-time status.

with the cost averaging about 2 percent of wages.

The regression results using the individually parameterized costs are reported in Table 6; the same nonlinear specification described earlier is used. In column (i) the cost is normalized by hours worked, and in column (ii) it is not normalized. Here, the results are reversed from the previous case; the shifting estimate is higher and more significant when cost is *not* normalized. When cost is normalized by hours, the estimate indicates 60-percent shifting, but the estimate is insignificant. When it is not normalized, the shifting estimate rises to 90 percent, once again indicating approximately full shifting to wages, and it is statistically significant.

One reason for the worse results when cost is normalized by hours could be the fact that hours per week in the March CPS are for the previous year, while in the May survey they are the usual hours per week worked currently. The May measure may be a less noisy proxy for actual hours, which makes the estimate of cost per hour more precise and reduces the problems that arise from dividing both the dependent and independent variables by hours. To address this point, as well as to reduce the possible spurious influence of low-hours workers who are not covered by health insurance, I focus only on individuals who worked 35 hours per week or more in column (iii). The non-normalized estimate is similar for this restricted sample, and it indicates shifting of about 75 percent of the cost of the mandate; it is significant at the 10-percent level.

The fifth row of Table 6 reports labor-input results for the individually parameterized costs. Here, the results are the opposite of those uncovered earlier; there is now a *fall* in hours and a *rise* in employment. However, both the hours coefficient and the employment coefficient are completely insignificant, and there is no net effect on labor input. This confirms the conclusion that, on average, the cost of the mandate was fully shifted to wages.<sup>33</sup>

<sup>33</sup>I have also performed the two specification checks described above for the federal law change. First, I

## V. Conclusions

Mandated employer provision of employee benefits is a topic of increasing interest in America today, and many of the proposed mandates are group-specific ones. When there is a market failure in the provision of a particular benefit, a mandate may be an efficient means of correcting the failure. By exploiting the fact that employees value the benefit that they are receiving, mandates act as a benefits tax, and can (in the limit) be as efficient as lump-sum financing of the benefit expansion. However, this argument rests crucially on the ability of wages to adjust freely to reflect employee valuation of the mandated benefit; in the case of group-specific mandates, there may be a number of impediments to such free adjustment of relative wages.

The evidence in this paper supports the contention that there will be group-specific shifting of the costs of mandates such as comprehensive health insurance coverage for maternity. This finding was robust to a variety of different specifications of the effect of these maternity mandates. The fact that the wages of women of childbearing age and their husbands were free to reflect the valuation of these benefits suggests that group-specific mandates do not change the relative cost of employing the targeted group of workers. This is an important precondition for arguing that mandates are an efficient tool of social policy.

It is important to highlight that this paper focused only on the efficiency case for mandates as a tool of public policy. In fact, there are at least two equity arguments

---

reran the regressions within each of four regions of the country: the Northeast, the Midwest, the South, and the West. Within each region, there was evidence of wage offsets, with the shifting estimates (from the regressions in which cost is not normalized by hours) ranging from 56 percent to 122 percent. However, none of the estimates was individually statistically significant, and none was significantly different from any of the others. Second, I controlled for industry-specific shocks by once again including industry-by-area-by-year controls. As with the earlier state laws, this had no effect on the coefficient of interest.

against mandates. First, the goal of the mandate may be to redistribute resources toward a certain group in society. In this case, group-specific shifting of the costs of a mandate undoes this redistributive policy. Second, mandates may be relatively regressive policies for financing benefit expansions. As Rodrigo Vergara (1990) shows, a tax on all labor which finances a benefit expansion will be more progressive than a mandate if the distribution of income is sufficiently unequal.

Furthermore, the case of maternity health benefits may illustrate how correcting one market failure can serve to exacerbate another. Health economists have shown that full insurance may lead to large welfare losses through the overutilization of medical resources (Martin S. Feldstein, 1973). Indeed, it is interesting to note that the number of cesarean births per 1,000 population doubled from 1975 to 1981 and that cesarean sections are now the second most frequently performed surgical procedure in the country (Health Insurance Association of America, 1989; U.S. Department of Commerce, 1990). More research is needed on the effects of increased coverage for maternity after the mid-1970's on the costs of childbirth. Did full insurance coverage lead to more costly treatment of the complications of childbirth?

Finally, this analysis has focused solely on the financing of expansions of insurance coverage and has ignored the potential benefits of mandates. If expanded coverage of maternity did lead to a change in the style of treatment of childbirth, this may have had beneficial effects on birth outcomes. Similarly, if maternity-leave provisions increase the continuity of labor-force participation of women, there could be important gains in terms of reducing workplace inequality. There have also been almost 1,000 other mandated benefits at the state level which are similar to these maternity mandates; that is, they dictate the inclusion of minimum levels of certain benefits in existing health insurance plans. Some mandates, such as mental illness and alcoholism treatment, may have substantial "offset" effects in terms of reducing medical expenditures in other parts of the health-care system

(McGuire and Montgomery, 1982). If these benefits can be estimated, they could be weighed against the wage costs to employees in evaluating the efficacy of future workplace benefit expansions.

## INTRODUCTION

The beneficial effects of foreign trade and foreign direct investment (FDI) on efficiency and growth are generally recognised, and there is a wide consensus that policy should aim at reducing or eliminating hindrances to global trade and FDI integration. Successive multilateral trade rounds, regional trade agreements and bilateral and multilateral investment accords have reduced formal barriers to trade and FDI. The current World Trade Organization (WTO) trade negotiations aim at continuing this trend. However, border barriers are still significant in some countries and industries, in particular in the form of restrictions to FDI. Moreover, there is growing recognition that policies aimed at non-border-related objectives may have a significant impact on the extent of trade and activities of multinational enterprises (MNEs). Thus, unnecessarily restrictive product and labour-market regulations can act as barriers to trade and FDI. The state of the domestic physical infrastructure can also influence countries' capacities to participate in the globalisation of economic activity.

This paper assesses the importance of certain border and non-border policy measures for global economic integration. A number of studies have looked at the influence of economic and/or policy factors on trade and FDI, but most of them tended to deal mainly with geographical and structural factors or focus on a small subset of policy variables (*e.g.* border variables). Building on previous OECD work, this paper takes into account a much broader set of policy variables, including product and labour-market regulation as well as openness to FDI and infrastructure supply. In addition, it looks at both FDI and trade, in a framework in which these two dimensions of global integration respond to similar structural and policy factors. The analysis covers FDI and trade in both goods and services, thus aiming to account for the most important channels of globalisation and dealing with most modes of cross-border service supply.<sup>1</sup> The aim of the paper is threefold:

- First, it describes trends in goods trade, services trade and FDI, as well as border and non-border policies that are likely to affect them. To this end, a large set of policy indicators constructed by the OECD is used, including the new summary indicators for FDI-specific regulations described in Golub (2003). Indicators of tariffs, non-tariff barriers and participation in free trade areas are also used to gauge the stance of policy toward trade openness.<sup>2</sup>

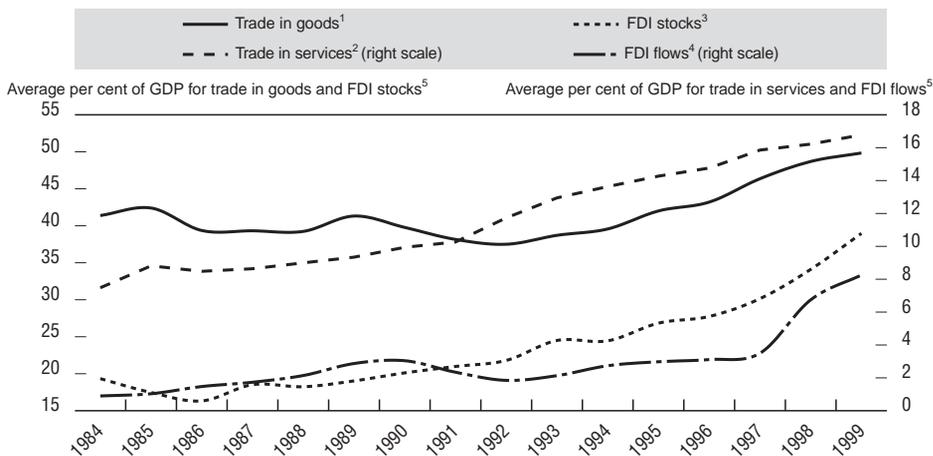

- Second, the paper estimates the impact of these policies on trade and FDI in a framework in which trade flows and the activity of MNEs are seen to be determined jointly and respond to the same market and policy influences.<sup>3</sup> The empirical analysis focuses on bilateral trade and FDI patterns, including bilateral trade in services, but also looks at the determinants of multilateral inward FDI to explain the overall ability of individual OECD countries to attract international investment.
- Third, using the results of the empirical analysis, the paper discusses and quantifies the effects on global integration of policies targeted at removing border and non-border barriers and levelling the playing field for FDI in the OECD area. In this context, the focus is on four widely-advocated policies: removing explicit restrictions to trade and FDI; promoting domestic competition; improving the adaptability of labour markets; and ensuring adequate levels of infrastructure capital. It should be noted at the outset that the results of the simulations are only suggestive of what could happen under different policy scenarios, notably because the empirically-estimated models on which they are based are partial equilibrium, reduced-form models that are unable to account for the general equilibrium interactions between policy changes and trade and FDI flows. Notably, to the extent that diversion effects are important, the simulation results may overestimate the effects of policy changes on the variables of interest.

The paper is structured as follows. The next section documents recent trends in foreign trade and internationalisation of production. The following sections, respectively: discuss the main factors that are likely to jointly affect trade and FDI patterns in OECD countries, focusing on the role of policy; present econometric evidence on the impact of these factors on trade and FDI; use the results of this analysis to perform policy simulations; and conclude. Details about empirical results (including their sensitivity to changes in empirical specifications) and the construction of the underlying data sets can be found in Nicoletti *et al.* (2003).

## RECENT TRENDS IN TRADE, FDI AND THE INTERNATIONALISATION OF PRODUCTION

Focusing on the OECD area, Figure 1 depicts stylised facts on what is commonly called “globalisation”. Over the past decade, both the trade intensity (defined as the sum of exports and imports over GDP) and the foreign investment intensity (defined as the sum of outward and inward FDI positions over GDP) have increased significantly in the average OECD country.<sup>4</sup> The upward trend was particularly pronounced since the early 1990s for FDI and trade in goods, which remained significantly more intense than services trade. The aim of this section is

Figure 1. Trade and FDI patterns in the OECD

1. Trade in goods is defined as the sum of exports and imports of goods realised between a reporting country and the OECD area.
2. Trade in services is defined as the sum of exports and imports of services realised between a reporting country and the world (due to the lack of OECD-specific data, services trade cannot be defined relative to the OECD area).
3. FDI stock is the sum of inward and outward positions of the average country in the OECD area.
4. FDI flows are the sum of yearly investment inflows and outflows of the average country to the OECD area.
5. Simple average of the ratios of OECD countries.

Source: OECD.

to illustrate the main cross-country and cross-industry features of these trends and highlight some of the questions that need to be addressed to understand the economic factors that underlie these phenomena as well as the role that policy can play in favouring the trend towards OECD-wide integration.

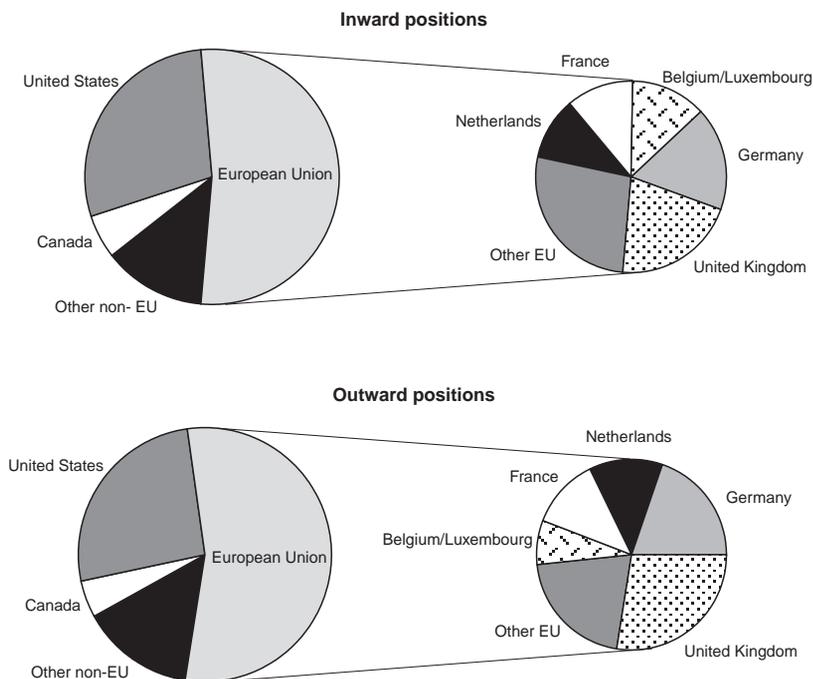

### Trends in FDI

Most global international investment activity goes on among OECD countries and takes the form of ownership changes in existing enterprises (mergers and acquisitions, privatisation), with so-called “green-field” investment playing only a minor role (OECD, 2002).<sup>5</sup> While different forms of FDI might respond to policies differently, the empirical analysis of the paper is based on aggregate financial FDI data since the identification of the different forms of FDI is not possible for many OECD countries. In 1999, the OECD accounted for around 91 per cent of world investment outflows and 74 per cent of world inflows (UNCTAD, 2001). Over the same period, EU countries combined were both the largest recipients and the

largest suppliers of FDI in the OECD area, followed by the United States, Japan, Canada and Switzerland (Figure 2).

The average share of FDI inflows in total business investment went from little more than 3 per cent over the 1980s to almost 11 per cent in the 1990s, bringing about a significant increase in the outward and inward positions of most OECD countries. Given the way these data are constructed (Box 1), part of this increase may be due to a revaluation of existing positions reflecting the sharp increase in equity prices over the same period (OECD, 2002c). Nonetheless, the upward trend in FDI flows points to a rising internationalisation of production over the 1990s. FDI activity dropped sharply in recent years, but most observers attribute the decline to transitory causes rather than to a reversal of the earlier decade-long upward trend.<sup>6</sup>

Figure 2. Distribution of OECD FDI positions in 1998<sup>1</sup>

1. The charts are based on bilateral data. As the method used for valuing FDI positions varies across countries, the resulting shares are undervalued for countries that report book values (e.g. the United States).

## Box 1. Trade and FDI data

### Foreign direct investment

Foreign direct investment is a category of international investment made by a resident entity in one country (direct investor) with the objective of establishing a lasting interest in an enterprise resident in another country (direct investment enterprise).<sup>1</sup> This involves both the initial transaction between the two entities and all subsequent capital transactions between them and among affiliated enterprises, both incorporated and unincorporated.

Conventionally, a foreign direct investment enterprise is an incorporated enterprise in which a foreign investor owns 10 percentage or more of the ordinary shares or voting power or an unincorporated enterprise in which a foreign investor has equivalent ownership. Financial FDI data may be geographically biased to the extent that MNEs use strategically-located holding companies to intermediate their investments.

Statistics on FDI transactions and positions are based on the OECD database developed by the Directorate for Financial, Fiscal and Enterprise Affairs (published under the title *International Direct Investment Statistics Yearbook*). These statistics are compiled according to the concepts used for balance of payments (flows) and international investment position (stocks) statistics. Both data sets are available for inward and outward investment with further breakdowns *i*) by partner country and *ii*) by economic sector (according to ISIC Rev. 3 classifications).

Generally, information on inward flows and stocks and on outward flows and stocks is available. The data set used in the empirical analysis covers 28 OECD countries (Luxembourg and Belgium report together; data for Slovakia are not included) over the 1980-2000 period and hence comprises 756 country-partner pairs per year for a potential of 15 876 observations. However, some countries are not yet able to provide complete sets of statistics and, therefore, the panel is unbalanced.<sup>2</sup> An attempt has been made to restore some of the missing data by using available antipodal bilateral data.

Substantial progress has been made towards the agreed international standards for FDI data compilation established by the IMF and the OECD. However, some OECD countries still deviate from the standards in terms of, for instance, the elements included in the disseminated data (income on equity, reinvested earnings and income on debt), the treatment of indirectly-owned investment enterprises or, to a minor extent, definitions used to identify direct investment enterprises resident in the reporting country. The majority of countries report data on investment positions based on book values, but some measure the positions in market values. These issues make the cross-sectional comparability of the data somewhat problematic.

### Foreign trade

Information on international trade has been collected from three sources. Data on trade in goods come from the OECD publication *International Trade by Commodity*

## Box 1. Trade and FDI data (cont.)

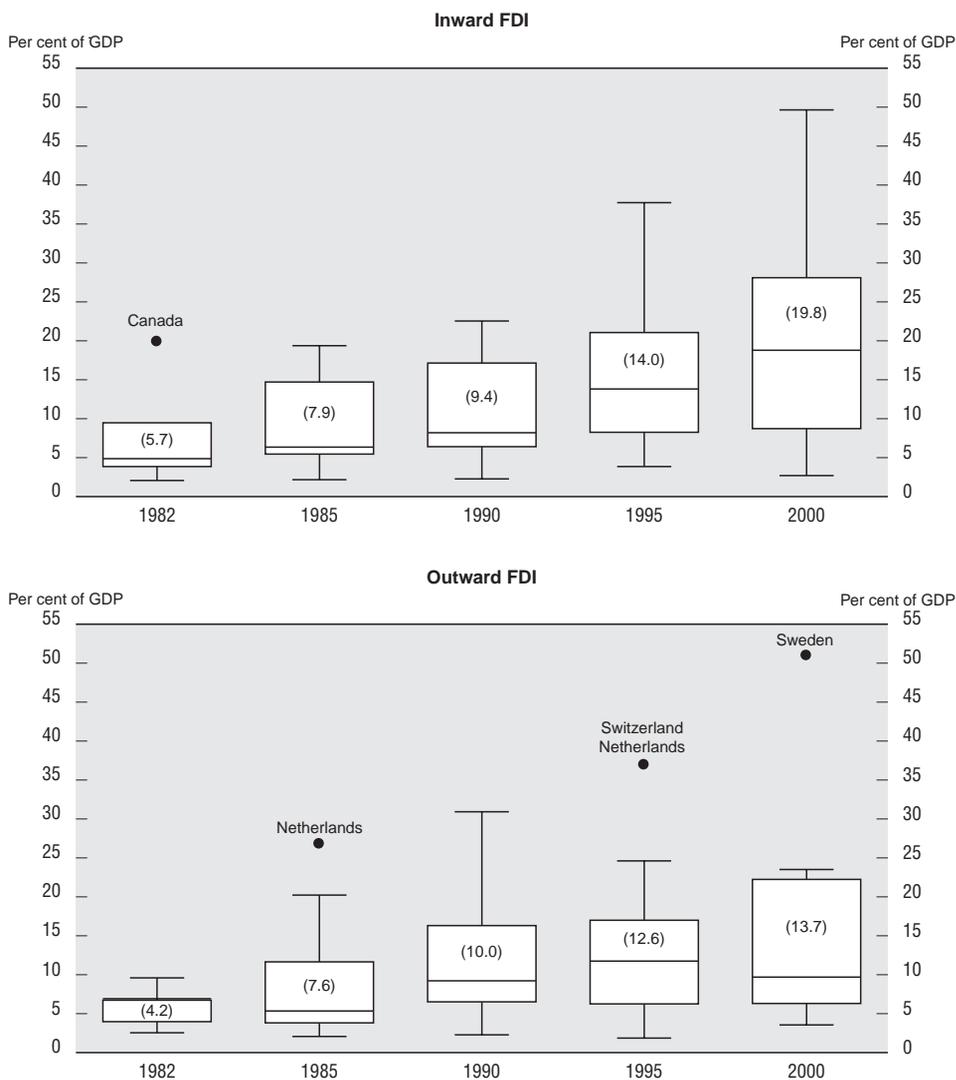

Statistics and match the same format as the financial FDI data, *i.e.* 28 countries and partners during the period 1980-2000. Information on trade in services with partner disaggregation has been taken from the OECD *Statistics on International Trade in Services* 1999-2000. Information is available for two years only, the data covering 20 countries and 27 partners.<sup>3</sup> Data on trade in services by sector (bilateral information is not available) are based on the OECD *Statistics on International Trade in Services* 1990-1999. These data have been so far used for descriptive purposes only.

1. "Lasting interest" implies the existence of a long-term relationship between the direct investor and the enterprise and a significant degree of influence by the direct investor on the management of the direct investment enterprise.
2. For the period 1980-2000, no geographic breakdown is available for the stock data for the Belgium-Luxembourg Economic Union, Spain, Ireland and Turkey; for outward stocks for Hungary and Mexico; and for outflows for Greece and Mexico.
3. Balance of payments statistics on services cover cross-border supply (*e.g.* freight and communications) and consumption abroad (*e.g.* tourism). They exclude the exchange of services that take place through commercial presence (*i.e.* the activity of foreign affiliates) and movement of individuals (*i.e.* temporary presence of service suppliers).

The general move towards internationalisation has been matched by an increasing cross-country dispersion of the amount of FDI supplied and hosted relative to the size of the investor and host countries (Figure 3). By the year 2000, the variances of the instock and outstock as ratios to GDP among OECD countries were larger than two decades earlier, though less so for outstocks. Figure 3 also shows that a number of host countries have relatively large instock ratios, while outstock ratios tend to be more evenly distributed across investor countries. Focusing on inward FDI positions, Figure 4 shows the average instock to GDP ratios of individual countries in the 1980s and 1990s. It suggests that the largest contribution to the increase in the cross-country dispersion of the OECD instock was provided by Ireland, Belgium and the transition countries, in which inward FDI surged during the 1990s.

The variance of the multilateral measures masks very different cross-country patterns at the bilateral level. First, in 1998 (the latest year for which bilateral data are reasonably complete) the number of host partners varied across investing countries, ranging from below 10 for Hungary and Turkey to above 20 for many EU countries, the United States and Canada. Second, the extent to which countries

1. Average values over the two periods. For countries where FDI position data are not available, values of bilateral stocks reported by their OECD partners were summed up to obtain an approximate measure of multilateral FDI stocks.

Source: OECD.

geographically specialise their FDI across a given number of partners also differs. While many countries tend to evenly distribute their FDI across partners, some of them (*e.g.* Canada, Korea, Denmark and the United Kingdom) tend to concentrate FDI on a few host countries. Similarly, some countries (Austria, Canada, the United Kingdom and Mexico) mostly host FDI originating from just a few countries.

The indicators depicted in Figure 5 report patterns of geographical specialisation focusing on inward (and outward) FDI from (to) the European Union, the United States and Japan – where specialisation is defined in terms of a country hosting (supplying) a share of FDI from an investor country (to a host country) larger than the share hosted (supplied) by the OECD. Geographical factors are clearly important in explaining patterns of FDI instocks (Panel A): most European countries specialise in hosting FDI originating from EU countries; Canada, Mexico and Ireland specialise in hosting FDI from the United States; and Pacific shore countries specialise in hosting FDI from the United States and/or Japan. Interestingly, however, the degree of geographical specialisation varies significantly both within the same area and relative to countries located outside the area. On the whole, the dispersion of specialisation patterns suggests that geographical factors are important, but they cannot explain the entire variability in the data.<sup>7</sup>

Figure 5. **Patterns of geographical specialisation in inward and outward FDI<sup>1</sup>**  
Average 1995-1998

1. Inward geographical specialisation is defined as the revealed tendency of a country to host a share of FDI from an investor country (European Union, Japan, United States), which is larger than the share hosted by the OECD as a whole. Outward geographical specialisation is defined as the revealed tendency of a country to invest a share of FDI in a host country (European Union, Japan, United States) which is larger than the share invested by the OECD as a whole. A country is "geographically specialised" in investing to (or in hosting from) another country if the indicator is above unity. For computational details, see Annex.

2. Data for FDI from Japan are for 1991-1994.

Source: OECD.

## Trade developments: goods and services

As pointed out in Figure 1, both goods and services trade flows rose faster than GDP over the past decade in the OECD area. At the same time, the intensity of trade in services remained much lower than in goods. Underlying these OECD-wide stylised facts are wide cross-country differences in export and import intensities and in the geographical specialisation of the exports of individual OECD countries.

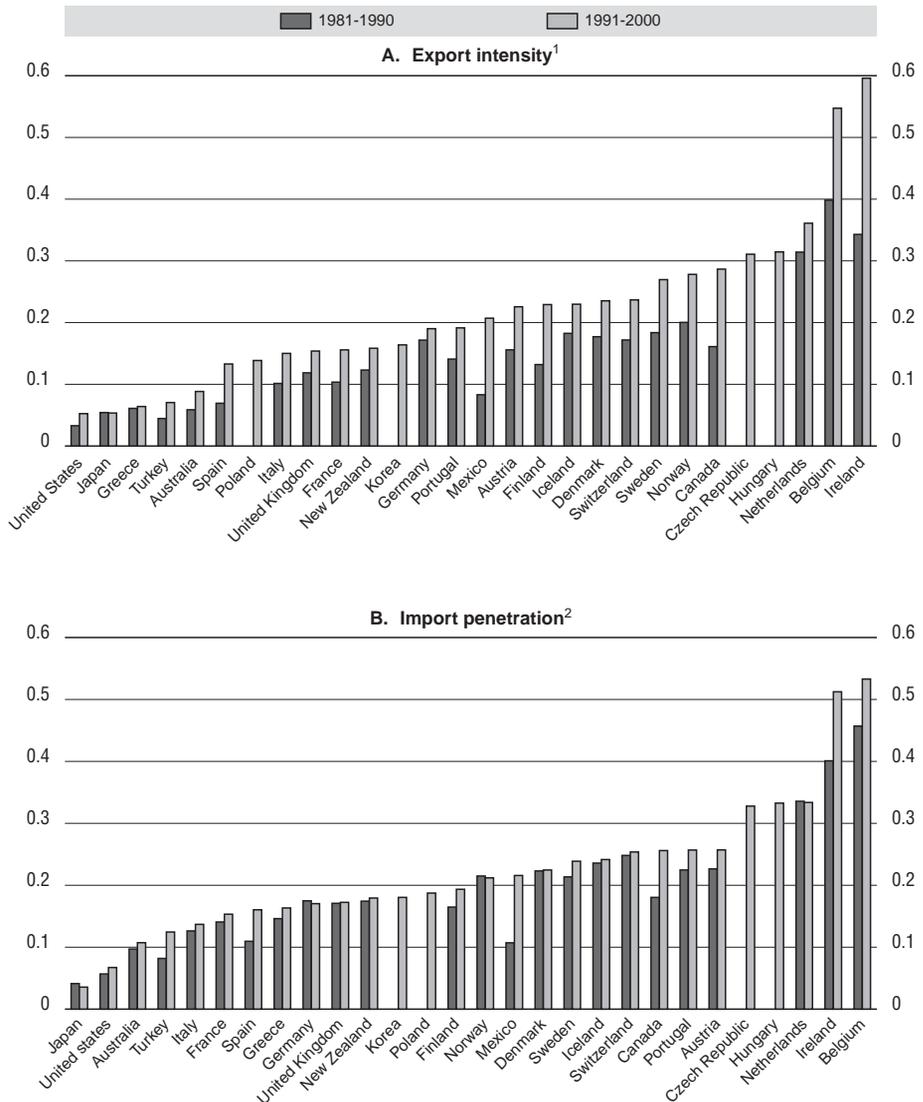

### *Goods trade*

Figure 6 shows average intensities of goods trade within the OECD area for individual member countries over the 1980s and the 1990s. The intensity of exports to OECD countries (defined as the share of exports in GDP) increased in all countries except Japan,<sup>8</sup> partly reflecting a stronger propensity of the Japanese economy to export to non-member Asian countries over the past decade (Panel A). The increase was particularly noticeable in Ireland and Mexico, which almost doubled their OECD export intensity between the two periods, but significant increases also took place in Canada and the northern European countries. It is also known that the increase in OECD export intensities over the 1990s has been marked for transition member countries.

The increase in trade intensities over the past two decades has probably been matched by rising intra-firm trade related to the widening role played by MNEs in the OECD area (OECD, 2002d). Indirect evidence of this is provided by the rising share of intra-industry trade, especially in transition countries, which parallels the sharp increase in FDI inflows over the same period. Direct measures of intra-firm trade, which are available for only a few countries (notably the United States, Japan and some Nordic countries), also point in this direction. The available data suggest that intra-firm trade among MNEs and foreign affiliates located in high-income OECD countries mainly involved the export of final goods for sale in local markets, reflecting horizontal-type FDI, while trade between MNEs located in high-income countries and their affiliates in middle-income OECD countries also involves imports of intermediate goods to be further manufactured and sold in the country of the parent company (or other countries), reflecting vertical-type FDI.

A cursory view at Figure 6 also suggests that both the location and the size of the countries are important factors determining the propensity to trade. For instance, economies that are large, such as Japan and the United States, or geographically remote relative to major OECD markets, such as Australia, have relatively low trade intensities, reflecting either a wide internal market or high transport costs. By contrast, economies that are small and well-connected to large

Figure 6. Intensity of goods trade within the OECD area, 1980s and 1990s

1. Export intensity is defined as the ratio of exports to GDP.

2. Import penetration is defined as the ratio of imports to domestic absorption.

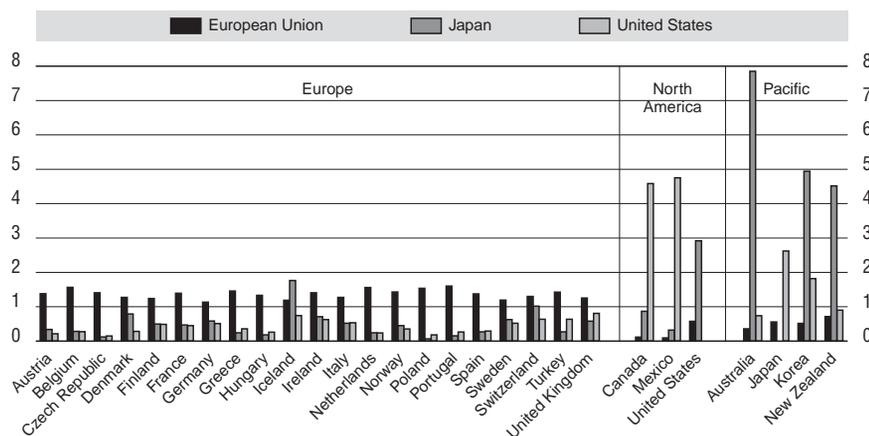

Source: OECD.

neighbouring countries, such as Belgium and the Netherlands, have high trade intensities. However, location and size cannot fully explain the cross-country patterns of export intensities, because there are small countries with low intensities, such as Greece, and relatively remote countries with higher intensities, such as New Zealand and Korea.

Using the same indicator as for FDI, Figure 7 shows the patterns of geographical specialisation over the 1990s in exporting to the European Union, Japan and the United States. The relative distance of each country from the three destinations seems to matter. Japan is the favourite destination of exports from Australia, New Zealand and Korea; and the United States is the favourite destination of exports from Canada and Mexico. Exports from European countries are more uniformly distributed, though still biased towards EU destinations. Clearly, as neighbouring countries are often linked by free-trade agreements (such as the EU Single Market or NAFTA), the transport cost effect underlying these patterns is likely to act in parallel with a free-trade area effect (see below). Indeed, develop-

Average of the 1990s

1. Geographical specialisation in goods trade is defined as the revealed tendency of a country to export a share of exports of its total exports to a partner country, which is larger than the share exported to that country by the OECD in total OECD exports. A country is "geographically specialised" when the indicator is above unity.

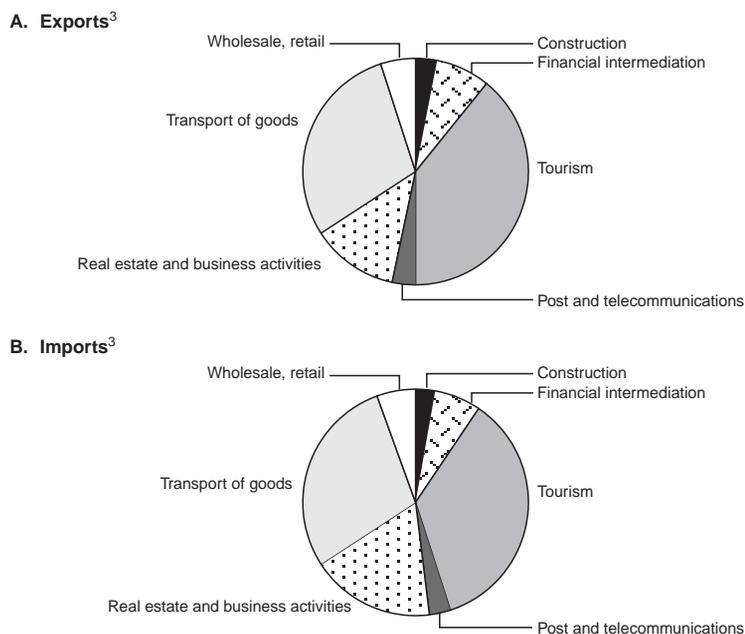

Source: OECD.

ments in both European and North American countries suggest that free-trade agreements such as the EU Single Market and NAFTA may have borne their fruits over the 1990s.

### Trade in services

Figure 8 shows the average industry structure of OECD trade in services in 1999 as recorded in balance of payments statistics on multilateral trade, which cover only a subset of modes of cross-border services supply (notably excluding commercial presence and movement of individuals) (see Box 1). According to these figures, most services trade, whether exporting or importing, relates to tourism (around 30 per cent) and transport (around 25 per cent), followed by business

Figure 8. **Composition of services trade in the OECD area,<sup>1</sup> 1999**

Source: OECD.

services (12 per cent) and financial services (6 per cent). The composition of services trade is similar at the individual country level. In other words, a large share of trade in services is related to international movements of people and manufactured goods. Yet, the most striking feature of services trade is that both export and import intensities are several times lower than the corresponding trade intensities for goods in all OECD countries for which data are available, with the ratio of manufacturing to services trade flows generally ranging from three to six in most countries. Even though such gaps could be narrowed once cross-border supply through commercial presence (*i.e.* FDI) is taken into account, differences in the trade intensities of goods and services are puzzling.

Lower services trade intensities are often related to the cost of transport, which is, for some services, much higher than the cost of shipping manufactured goods.<sup>9</sup> Also, the influence of geographical and structural factors, such as location and size of the economy, on trade in services and goods may differ. Cross-country patterns of export intensities and import penetration ratios suggest that these factors play partly the same role as for trade in goods (Figure 9). Trade is strong in relatively small and well-located countries – such as Austria, Belgium, the Netherlands and Ireland – and weak in relatively large or remote countries – such as the United States, Japan and Australia. However, these patterns are less clear than for goods trade and, indeed, the cross-country correlation between export intensities in goods and services is relatively low (around 0.2), though the correlation of import penetration ratios is higher (around 0.6). This suggests that other forces are impinging on the openness of OECD economies to trade in services.

### **Twin developments in FDI and trade**

The discussion of trends and patterns in FDI and trade offers *prima facie* evidence that the two phenomena are closely linked: both increased sharply over the past decade; both seem to be at least partly affected by factors related to distance, location and size of the economy; and in some cases trade openness seems to go hand in hand with high FDI and foreign affiliate activity, such as in Ireland and Belgium. Table 1 provides further evidence concerning this stylised fact at a finer level of detail. It reports the correlations between different measures of bilateral trade and bilateral FDI over the period 1980-2000 as well as in sub-period averages. All correlations are positive and significant at conventional levels, with particularly high coefficients between trade measures and FDI outstocks and instocks.

Although these correlations may imply a testable hypothesis that to some extent trade and FDI may be driven by the same set of economic factors, they are not necessarily evidence in favour of complementarity between FDI and trade. As discussed in the next section, at the firm or industry level the relation-

ship between FDI and manufacturing trade crucially depends on whether FDI is aimed at accessing foreign markets or fragmenting production in stages. Aggregate evidence concerning FDI and trade is, therefore, the result of conflicting influences and may only be interpreted as suggesting that, overall, one type of FDI dominates the other or, alternatively, that both FDI and trade are correlated to a third variable (*e.g.* income). By contrast, services trade and FDI can be expected *a priori* to be complementary, because establishing commercial presence abroad generally brings stronger services trade in terms of transport (*e.g.* supplying goods to foreign affiliates in the distribution sector), communications (*e.g.* data transactions with foreign affiliates in the financial, telecommunications or tourism sectors), etc. FDI in the services sectors indeed accounted for up to 65 per cent of total FDI flows (OECD, 2002c). In this connection, it is interesting to note that, among the correlations in Table 1, those between FDI and services exports and imports (which due to lack of data focus on the most recent period) are the highest.

## POLICY AND OTHER DETERMINANTS OF TRADE AND INTERNATIONAL INVESTMENT

Two broad sets of factors jointly affect trade and FDI: *non-policy factors* – including the effects of gravity (*e.g.* market size and distance) and factor proportions (*i.e.* relative endowments of different inputs) – and *policy factors*. The influence of these factors (*i.e.* the sign of the relationship and its intensity) is not necessarily the same across FDI and trade. In particular, it may depend on whether FDI is of the horizontal or vertical type (Box 2). Moreover, their influence may also differ in some cases across trade in goods and trade in services.

With an eye to the interdependency between trade and FDI, this section principally looks at key policy factors, grouping them into four categories: openness, product-market regulation, labour-market arrangements and infrastructure.<sup>10</sup> Some of these policy channels restrict market access by exporters and foreign investors. For instance, non-tariff barriers and FDI restrictions raise border obstacles to trade and investment. Other border and non-border policies make trade and investment unprofitable, for instance by increasing the relative cost of foreign *versus* home goods (*e.g.* tariffs or regulations that raise production costs) or decreasing the net returns of MNEs when they invest abroad. Finally, policies can also raise the overall cost of the transaction by affecting the costs of inputs that both the exporter and importer must use in order to implement the exchange (*e.g.* transport or communication services). Alternatively, policies can facilitate trade and FDI, for example by creating areas of free trade, improving the business environment in which exporters and MNEs operate or reducing the cost of transactions through the development of the necessary infrastructure.<sup>11</sup> This section shows by means of newly-developed indicators that approaches often differ across countries in each of the four policy categories and, when possible, offers *prima facie* evidence that these differences may be relevant for trade and FDI.

### Openness

As noted above, openness of a country to trade and FDI is assessed here in terms of policies that create (or eliminate) border barriers for exporters or investors, measured by indicators of tariff and non-tariff barriers, statutory restrictions to FDI and multilateral agreements that create areas of free trade among signatory countries.

#### **Tariff and non-tariff barriers**

Figure 10 reports the evolution of average (import-weighted) most-favoured-nation (MFN) tariff rates and import coverage of non-tariff barriers from 1988 to 1996, the latest year for which time-series data are available.<sup>12</sup> The conclusion

<sup>24</sup>

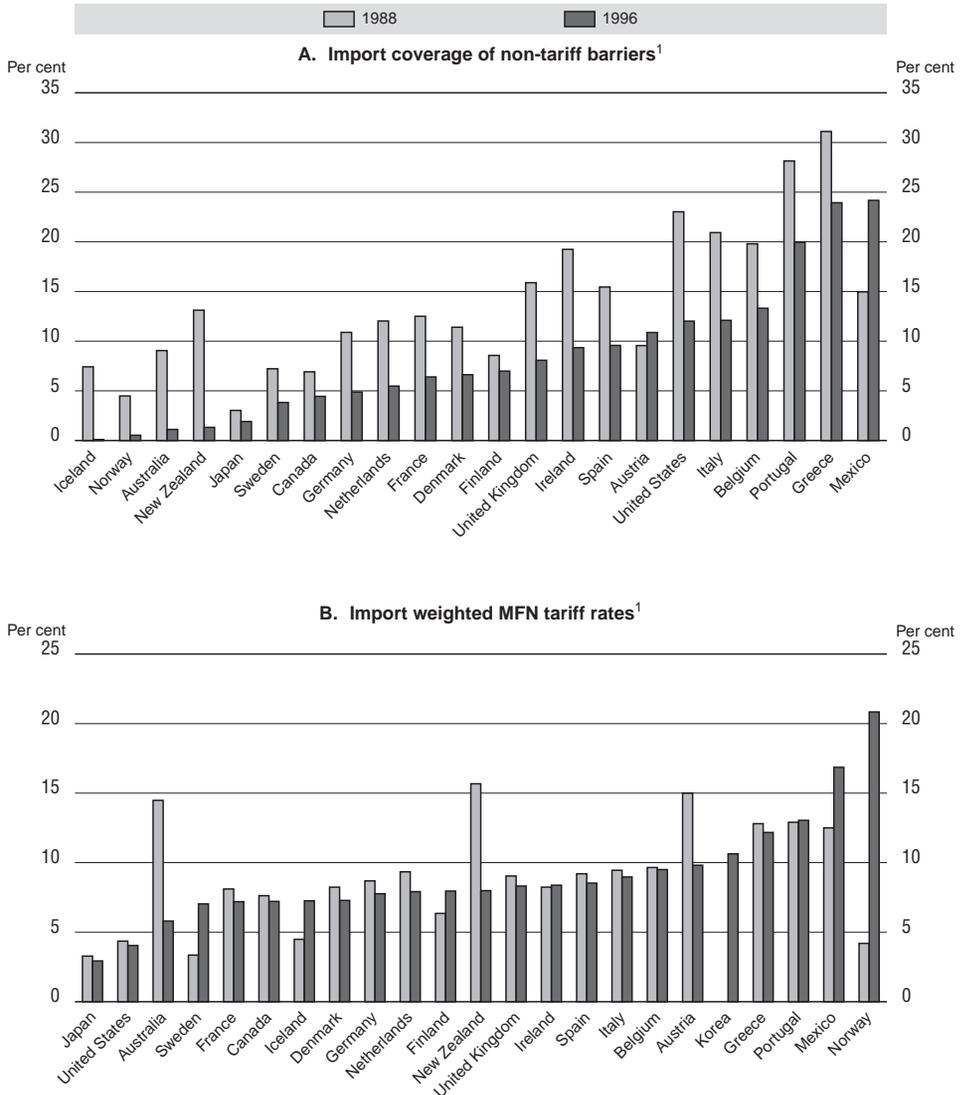

**Box 2. Trade and different types of FDI**

As pointed out by recent research, the interdependence of trade and FDI derives from the fact that the decision to export or invest abroad for producing locally is increasingly taken by the same unit, the multinational enterprise. This is clearest in the so-called “knowledge-capital” theory of the MNE (Markusen, 2002; Markusen and Maskus, 2001), which builds on previous work by Dunning (1981) and Buckley and Casson (1985). This theory notes that three types of firms exist in each country: purely domestic firms, which have headquarters and plants that produce only at home for local or export markets; the horizontal MNEs, which have headquarters at home and production plants both at home and abroad that produce the same goods; and the vertical MNEs, which fragment different stages of production by having headquarters at home and production plants in different foreign countries that produce different intermediate or final goods. Since the objective of the horizontal MNEs is to access foreign markets, trading or investing abroad are two substitute activities. They will choose one or the other depending on their relative returns, which depend among other things on the cost of trade, the cost of FDI and the firm-level economies of scale they can enjoy by duplicating production plants in foreign countries.\* By contrast, the objective of vertical MNEs is to take advantage of cross-country comparative advantage patterns by locating plants in different countries in order to specialise in different stages of production. Therefore, trade and FDI are complementary activities: vertical MNEs will typically export components to foreign affiliates and re-export to the home (or other) markets the goods produced abroad. Recent evidence suggests that horizontal MNEs may be prevalent in the OECD area, partly reflecting the increasing similarity in factor costs and endowments among member countries (OECD, 2002d). However, MNEs’ strategies have also been shown to vary across OECD countries, with horizontal strategies dominating in the United States (Markusen and Maskus, 1999) and vertical strategies dominating in Sweden (Mathä, 1999) and France (Soubaya Camatchy Ariguelou, 2002). See OECD (2002e) for a discussion of the relationship between trade and FDI.

\* Firm-level economies of scale arise when two-plant firms have fixed costs that are less than the double those of a single-plant firm. Firm-level economies of scale and trade costs are crucial elements for explaining the existence of horizontal FDI, as first pointed out by Markusen (1984).

of global and regional trade agreements (Box 3) during this period was reflected in a decline of both non-tariff and, to a lesser extent, tariff barriers within the OECD area. However, cross-country differences in average barriers still persist. Indeed, using a recent data set that includes a wider set of tariffs at the bilateral level, Figure 11 shows that in 2001 the dispersion of average (unweighted) applied tariff

### Box 3. Trade agreements

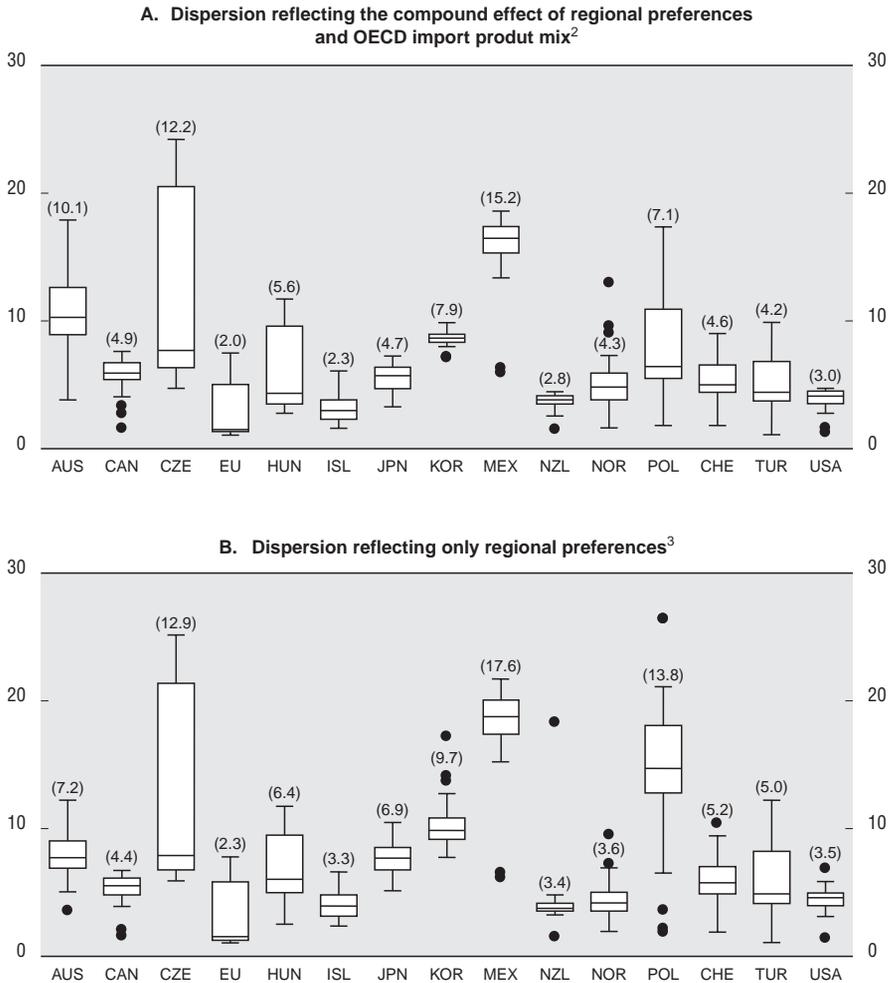

Almost all countries participate in one or more regional agreements, either as regional members or by virtue of bilateral agreements between regional groups and individual countries. In addition, there are bilateral agreements between countries (*e.g.* the accord between the United States and Chile). These agreements involve preferential trade provisions. However, the degree of integration they imply varies considerably. The main agreements can be classified, in order of increasing integration, as follows:

1. *Agreements to consult and co-operate*, without any binding harmonisation of policies, such as the Asia Pacific Economic Co-operation Group (APEC), signed in 1989, or the Association of South-East Asian Nations (ASEAN), signed in 1967 (whose members are currently planning to create a free trade area).
2. *Free-trade areas*, in which trade is liberalised within the group, but no common external tariff is adopted, such as the North American Free Trade Agreement (NAFTA), signed in 1994, the European Free Trade Area (EFTA), signed in 1960, and numerous bilateral agreements. Such arrangements require the establishment of rules of origin for imported products. They may cover different sets of transactions and imply different levels of integration among signatory countries. For instance, NAFTA includes both trade and FDI provisions.
3. *Customs unions*, whose members agree to common external tariffs, such as Mercado Común del Sur (MERCOSUR), signed in 1995, and several other agreements in developing countries.
4. *Common markets*, with free movement of labour and capital, and where economic integration transcends a customs union towards a fuller harmonisation of economic regulations, such as the 1992 European Single Market.
5. *Economic unions*, involving full harmonisation across a range of economic policies, a direction taken in 1998 by the European Union with the Maastricht treaty and the single currency.

Economic theory suggests that preferential trade liberalisation can increase welfare when it results in “trade creation” – trade that is consistent with comparative advantage – or reduce welfare in the case of “trade diversion” – when trade is diverted to less efficient partner countries. Dynamic gains resulting from scale economies and increased competition are also important, as is the potential for “deeper integration” amongst participating countries. On the other hand, complex rules of origin can lead to high administrative costs and possibly corruption. Another point of contention is whether regional blocs are “building blocks” or a “stumbling blocks” towards multilateral liberalisation. Regional integration is, in principle, contrary to the fundamental GATT/WTO principle of non-discrimination, but the WTO does allow such agreements in practice as long as substantially all trade is liberalised (art. XXIV). For more details, see OECD (2001c and 2002f), Panagariya (1999) and Hoekman and Schiff (2002)

rates was indeed wide across OECD country pairs. This reflects tariff discrimination across trading partners, which may well contribute to explaining differences in bilateral trade intensities among OECD countries.<sup>13</sup>

Trade agreements tend to match and accentuate the gravity forces (see below) that affect bilateral trade among signatory countries.<sup>14</sup> The positive influence of free-trade areas on trade could be less pronounced for services, since non-border barriers may be more relevant for this kind of products. Suggestive evidence on the positive effects of regional agreements on bilateral goods trade flows among signatory countries is provided in Figure 12, which shows the change in geographical specialisation of exports to the European Union, the United States and Japan over the past two decades. With a few exceptions, EU countries have increased their specialisation towards the European Union, probably reflecting increasing market integration under the Single Market Programme.

In addition to influencing trade openness, tariff barriers can also affect bilateral FDI relationships. Vertical FDI aimed at re-importing to the home country or

exporting to third-party countries the final or intermediate goods produced by foreign affiliates can be depressed by high bilateral tariffs between the host and investor country or between the host and third-party countries. On the other hand, high bilateral tariffs can generate so-called “tariff-jumping” behaviour by MNEs. Horizontal FDI that is prompted by tariff-jumping could be positively related to the level of tariffs in the host country. The same kind of relationship could *a fortiori* be expected between horizontal FDI and non-tariff barriers, since the latter often raise absolute barriers to market access (*e.g.* quantitative restrictions). Therefore, non-tariff barriers are likely to have a positive effect on FDI.

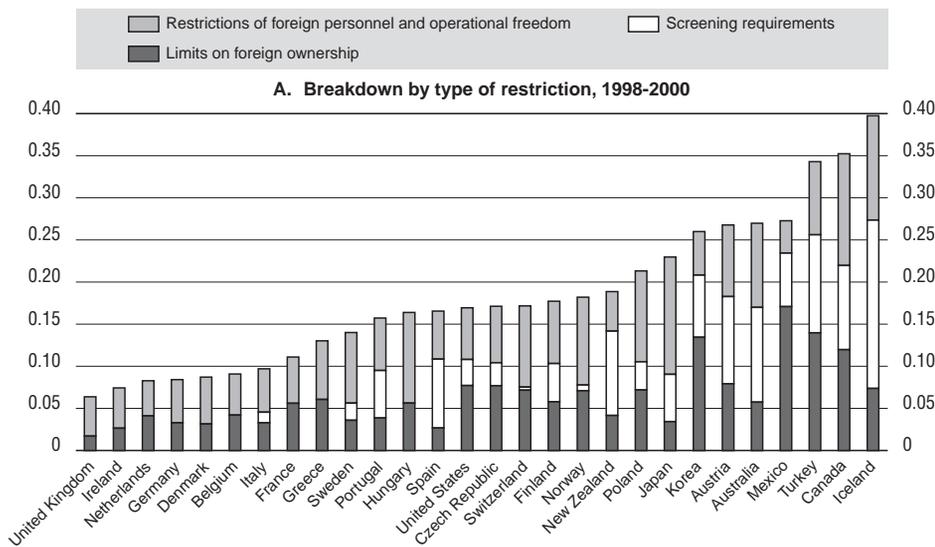

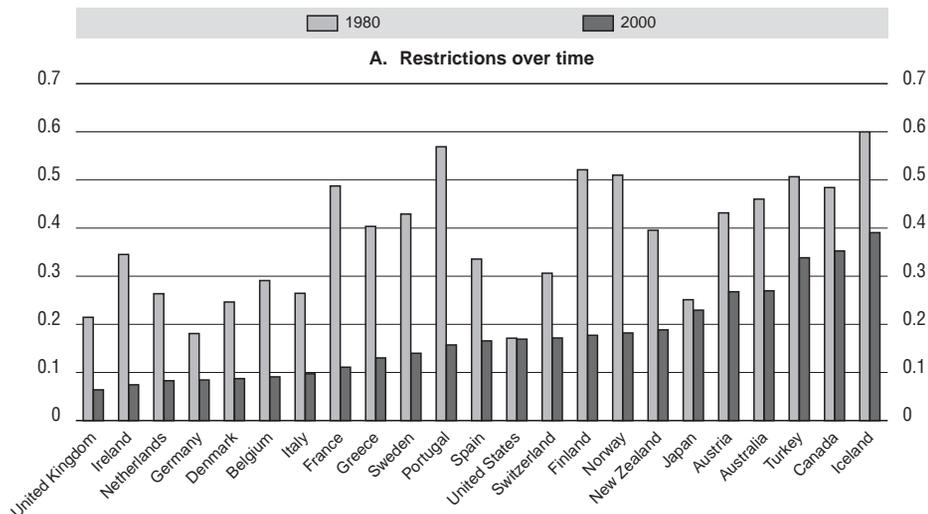

The effect of free-trade agreements on bilateral FDI transactions is more complex.<sup>15</sup> By substantially lowering trade costs among signatory countries, free-trade agreements make trade more advantageous than local production, tending to reduce horizontal FDI flows at any given level of fixed costs. However, by enlarging the overall size of the market in the free-trade area, these agreements also increase the scope for reaping firm-level economies of scale through horizontal FDI.<sup>16</sup> Moreover, the reduction in trade costs tends to increase vertical FDI flows that are aimed at re-exporting products into the home country or into other signatory countries. Furthermore, free-trade agreements tend to have a positive effect on horizontal FDI flows from non-signatory countries, because they enlarge the size of the market that they can access by producing locally at any given level of trade costs.<sup>17</sup> In conclusion, the effect of free-trade agreements on FDI flows among signatory countries is ambiguous, while it is presumably positive on FDI flowing from non-signatory countries. These effects are empirically tested in the next section.

### **FDI restrictions**

Although formal international agreements on FDI have been far less extensive than on international trade, global negotiations and regional free-trade agreements often cover some aspects of international investment as well (*e.g.* capital-market liberalisation within the European Union and provisions on commercial presence in the GATS), generally leading to lower barriers to FDI. Moreover, a number of bilateral investment treaties have been signed among OECD countries, aiming at curbing barriers to FDI. A new set of indicators of FDI restrictions was assembled by the OECD to summarise and quantify such barriers and their evolution over time. The indicators, which are described in detail in Golub (2003), cover mainly statutory barriers, ignoring most of the other direct or indirect obstacles impinging on FDI, such as those related to corporate governance mechanisms and/or hidden institutional or behavioural obstacles that discriminate against foreign firms.<sup>18</sup>

According to these indicators (Figure 13), liberalisation of FDI flows has been substantial over the past two decades in all OECD countries except the United

<sup>30</sup>

Figure 13. FDI restrictions in OECD countries,<sup>1</sup> 1980-2000

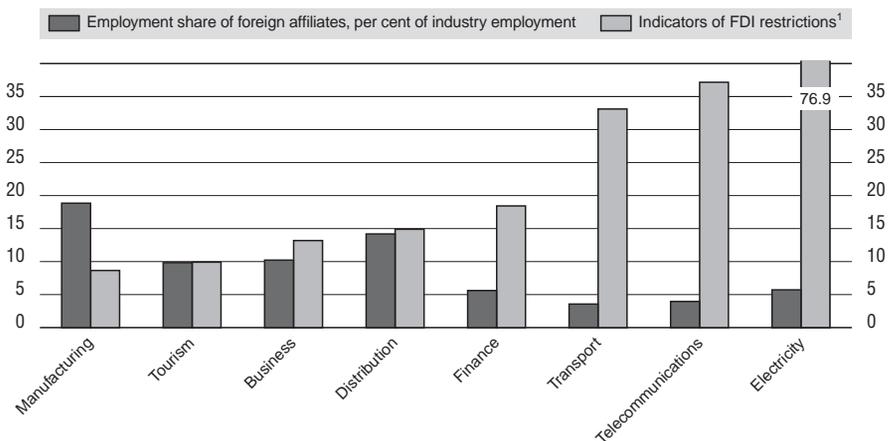

1. The indicator ranges from 0 (least restrictive) to 1 (most restrictive). The most recent year for which data are available varies across countries between 1998 and 2000.

Source: Golub (2003).

States and to a lesser extent Japan, both of which had relatively low statutory restrictions to begin with.<sup>19</sup> Despite the easing of restrictions and their generally much lower level at the end of the 1990s, cross-country differences remain significant, with most EU countries showing greater openness than the United States and Japan, and a few OECD countries maintaining a relatively restrictive approach (Iceland, Canada and Turkey). In most countries, restrictions on control of domestic firms by foreign residents (through either ceilings on foreign-owned equity or limitations on management and business choices) dominate those related to screening procedures (*e.g.* economic benefits or national interest tests).<sup>20</sup> On average, the bulk of restrictions are found in non-manufacturing industries.<sup>21</sup> FDI inflows into manufacturing are almost completely unrestricted, aside from economy-wide restrictions such as notification or screening requirements. Within non-manufacturing, electricity, transport and telecommunications are the most restricted industries, followed by finance, while the other service industries are on average relatively unrestricted.

Variable FDI restrictions across countries, industries and time are a natural candidate for explaining the dispersion observed in bilateral FDI transactions. These restrictions clearly raise barriers to foreign investment of MNEs and are likely to influence their choice among different investment locations. Some evidence of this is provided by Figure 14, which suggests that in very broad terms

Figure 14. **Foreign affiliates and FDI restrictions in the selected industries**  
OECD average

Source: Golub (2003) and OECD.

there is a weak but visible inverse relationship between the sectoral shares of employment in foreign affiliates and the level of FDI restrictions across a number of selected sectors.<sup>22</sup>

FDI restrictions may also be expected to influence bilateral trade much in the same way as tariff barriers are expected to influence bilateral FDI. By increasing the fixed costs of local production, they may make it *ceteris paribus* more profitable for horizontal MNEs to access local markets through exports. However, they also tend to decrease vertical FDI and the related export flows. Therefore, the aggregate effect on goods exports is ambiguous *a priori*. FDI restrictions represent an obstacle to services trade because they hinder service provision through commercial presence (through the establishment of foreign affiliates) and could also affect other modes of services trade because exports and commercial presence are complementary in certain industries, such as tourism.

### **Currency unions**

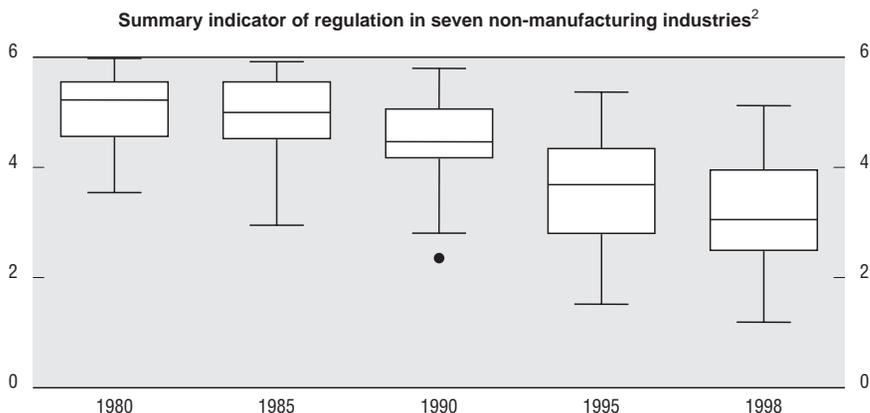

Exchange-rate variability may increase the transaction costs involved in trading goods and services and the risk premia on the returns to FDI. By eliminating those costs and reducing investment risk, currency unions can be expected to increase trade flows and expand FDI. Theoretical and empirical research has shown, however, that the impact of exchange-rate variability on trade is uncertain (for reviews, see McKenzie, 1999, and Taglioni, 2002), though recent evidence tends to find a positive effect of currency unions (Rose, 2000). At the same time, as suggested by Cushman (1985), the effects of reduced exchange-rate volatility on FDI depend on whether the firm sells its output in the host country or abroad, uses the host country or foreign inputs and finances its capital at home or abroad.<sup>23</sup> Therefore, the effect of exchange-rate variability on FDI is ultimately an empirical issue.

### **Product-market regulation**

Using a summary indicator of regulatory reform that ranks regulations in seven non-manufacturing industries from least to most restrictive of competition, Figure 15 suggests that OECD product markets have become increasingly open to competition over the past two decades. At the same time, the cross-country dispersion in regulatory approaches has increased, due to differences in initial conditions and/or in the scope and pace of reforms implemented by OECD countries. As a result, in 1998 (the last year for which cross-country regulatory data are available) regulations still differed substantially both at the economy-wide level and, especially, at the industry-level in several non-manufacturing industries.<sup>24</sup>

Product-market regulations can affect foreign trade and FDI in multiple and at times conflicting ways. Here, the focus is on regulations in the exporter (investor)

Figure 15. **Regulatory reform in OECD countries,<sup>1</sup> 1980-1998**  
 Summary indicator of regulation in seven non-manufacturing industries<sup>2</sup>

1. The box plot shows, in each year, the median OECD value of the regulatory indicator (the horizontal line in the box), the third and second quartiles of the cross-country distribution (the edges of each box) and the extreme values (the two whiskers extending from the box). Dots identify outlier observations.

- Source: Nicoletti and Scarpetta (2003).

country or the importer (host) country that curb market forces where competition is viable and/or impose unnecessary costs on the firms involved in the bilateral trade (or investment) transaction.<sup>25</sup> Domestic regulation generally does not discriminate between local and foreign firms, but it may have distorting effects on bilateral trade and FDI flows by affecting the relative prices of different products (*e.g.* tradable *versus* non-tradable or home *versus* foreign) or the relative rates of return expected from investing in different locations.

A way in which relative prices can be affected is when the introduction of anti-competitive regulation in one country increases its production costs, for instance by discouraging efficiency enhancements and productivity growth. In the short run, this tends to make the products exported by this country less competitive in foreign markets. Conversely, cost-increasing regulation in the importer country may tend *ceteris paribus* to make the products supplied by the exporter country more competitive. With wage, price or exchange-rate rigidities, these effects may tend to carry over to the medium to long run. Moreover, cost-increasing regulations (which usually differ across industries) may also induce a reallocation of resources in both the exporter and importer countries, affecting their respective abilities to trade. Another way in which regulations can affect trade patterns is by

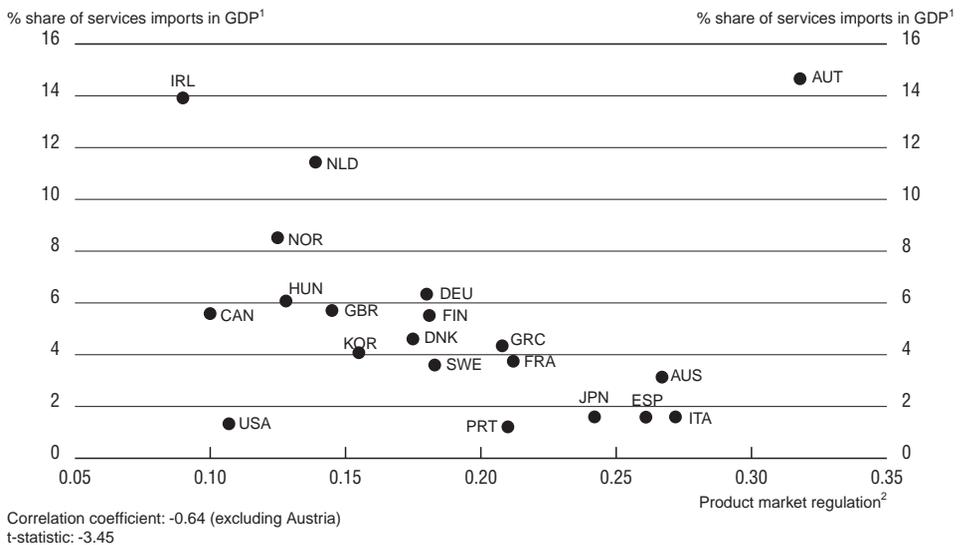

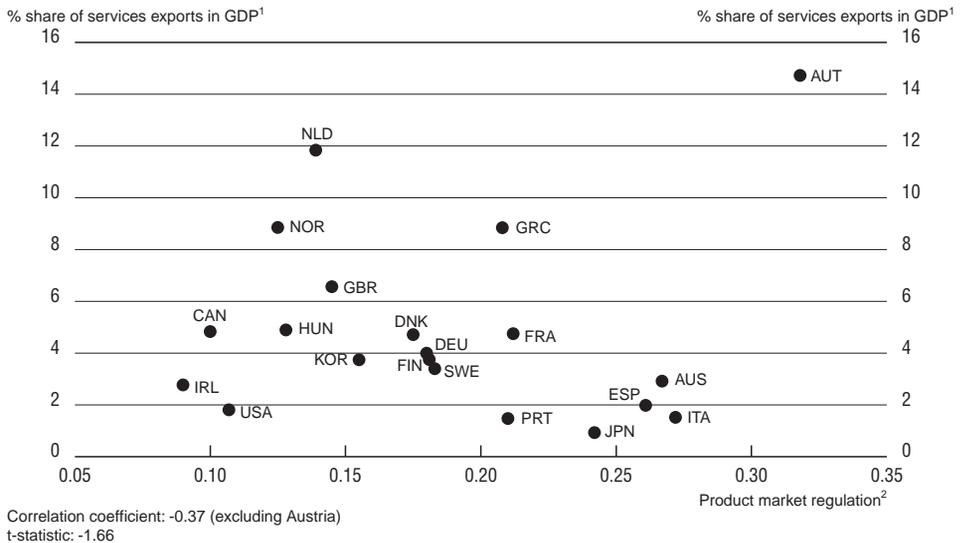

raising barriers to entry that reduce the number of suppliers, and hence the number of different goods offered, in an export market. This may have negative repercussions on intra-industry trade. Thus, strict product-market regulation in the foreign country potentially has conflicting influences on exports from the home country: on the one hand, it may stimulate exports through a competitiveness effect (at least in the short run); on the other hand, it may depress exports by limiting access to the foreign market.

A joint negative influence on bilateral trade can be exerted, in both the source and destination countries, by cost-increasing or barrier-raising regulations that affect industries in which inputs from both countries are needed to produce the traded product. This is the case, for instance, of many traded services – such as transportation, communications and business services – in which capital and labour from both the exporter and importer country are used to supply the service. In these situations, it is the combination of regulations in the countries involved in the transaction that is likely to affect trade flows.<sup>26</sup> Suggestive evidence of a negative correlation between anti-competitive services regulation and the intensity of services trade is provided in Figure 16, which plots the services export and import intensities of OECD countries against a summary indicator of regulation in non-manufacturing (which is increasing in restrictions to competition).<sup>27</sup>

Product-market regulations can also influence FDI by raising production costs or entry barriers, but their effect is more ambiguous:

- Cost-increasing regulations in the host country can deter FDI by lowering its expected rate of return if the foreign subsidiary is used as a platform for re-exporting final or intermediate goods back home or to other less regulated countries (the case of the vertical MNE). However, if FDI aims at accessing the local market (the case of the horizontal MNE), cost-increasing regulations in the host country may encourage FDI because the foreign affiliate can take advantage of the production structure of the parent firm, which may be more efficient than in local firms if regulations in the home country are more pro-competitive. Cost-increasing regulations in the home country may also stimulate outward FDI by favouring the delocalisation of production plants in countries with less costly regulations. On the other hand, the costs implied by these regulations may cripple the ability of home-country firms to internationalise production to the desired level.<sup>28</sup>
- Similar conflicting influences can be exerted by regulations that raise entry barriers in host countries. Such entry barriers clearly deter “greenfield” FDI aimed at establishing new firms or creating new production plants. However, by endowing local firms with market power, they can actually encourage inward FDI aimed at acquiring (or merging foreign parents with) existing local firms.

- Source: Nicoletti and Scarpetta (2003) and OECD.

Despite the potentially conflicting linkages between regulation and FDI, *prima facie* evidence suggests that, on the whole, barriers to entry and cost-increasing regulations in the host country, as summarised by the product of the 1998 indicator of economy-wide regulation with the summary 1980-1998 indicator of barriers to entry in seven non-manufacturing industries, are inversely related with the intensity of inward FDI in OECD countries over the 1980-2000 period (Figure 17).

### Labour-market arrangements

A wide set of policies and institutions affect the functioning of the labour market impinging on trade or FDI transactions. In this study, the focus is restricted to employment protection legislation (EPL), collective bargaining mechanisms and labour income taxation, for which comparable cross-country data are available.<sup>29</sup> The OECD (1997c, 1999) has extensively documented cross-country differences in labour-market policies and institutions. Both employment protection and labour income taxation are driven by important policy objectives, but could also have side effects on the level and geographical allocation of trade and FDI.

The main channel through which EPL and labour tax wedges can affect trade and FDI is the influence they may have on the adaptability of labour markets and

on the cost of labour.<sup>30</sup> In the absence of offsetting mechanisms, EPL and labour taxes can affect trade and FDI patterns for largely the same reasons as cost-increasing product-market regulations do, *i.e.* by adversely affecting the relative prices of different products, or by adversely affecting relative returns from investing in the country that has stringent EPL or high wedges.<sup>31</sup>

However, the effects of EPL and labour income taxation on trade and FDI may also depend on the regime of industrial relations in place in each OECD country. Previous research has shown that some collective bargaining arrangements can provide an effective offsetting mechanism for the costs implied by labour income taxation and EPL. Specifically, regimes in which bargaining is done at the national (*i.e.* centralised) level and with a tight co-ordination among employers and unions operating in different industries may make it possible to shift the implicit costs of wedges and EPL onto wages, much in the same way as may happen in decentralised and uncoordinated labour markets, provided wage resistance is not encouraged through other arrangements (such as high income replacement rates in unemployment benefit systems).<sup>32</sup> Thus, to the extent that this offsetting mechanism is operating, effects of EPL or tax wedges on trade and FDI should be found mainly in situations in which bargaining is neither co-ordinated nor decentralised, as it is found for instance in countries where negotiations are implemented at the industry level.

The potential offsetting mechanism provided by certain bargaining institutions is likely to be effective for neutralising the adverse effects of high EPL and tax-related costs in the home country on the relative prices of tradable vs. non-tradable goods. Its offsetting effect on the tendency of international investors to divert investment towards locations in which risk-adjusted expected returns are relatively low is more doubtful. This is because strict EPL is likely to affect not only the returns expected from foreign investment (*e.g.* through effects on labour costs that can be offset by bargaining institutions) but also their variability (*e.g.* by influencing the capacity of foreign affiliates to respond to supply or demand shocks), thereby increasing the risk that investors face in the host country. Since MNEs can choose *ex ante* where to locate their investment, they may still tend to move where the risk/return ratio is lowest, independent of the features of bargaining institutions in potential host countries.<sup>33</sup> Similarly, the potential for shifting the costs implied by labour taxation onto wages may be limited in MNEs whose highly-skilled employees and managers are likely to be more mobile across borders than their homologues in local firms.

## Infrastructure

Trade and FDI may also be affected by factors that are, or have been, closely-related to government policies regarding transportation, communica-

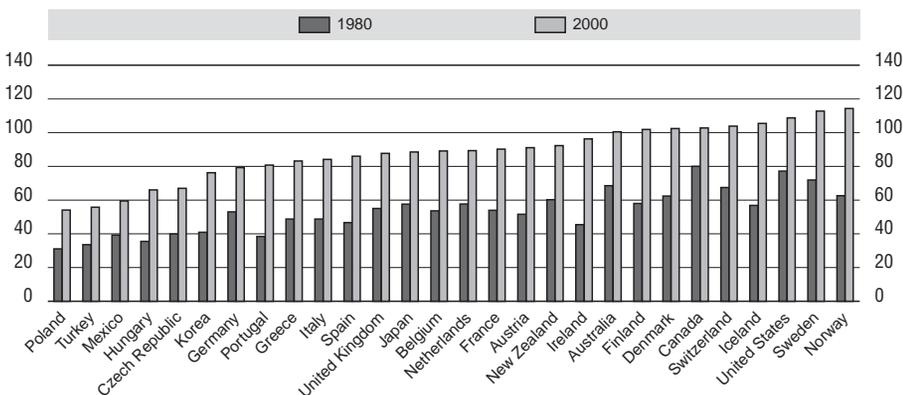

---

<sup>38</sup>

tions and energy supply. Indeed, due to their public good and natural monopoly characteristics, some fixed network infrastructures are financed through public investment.<sup>34</sup> Figure 18 uses a new set of indicators to show the evolution of infrastructure endowments of OECD countries over the past two decades. The indicators are increasing in the quality and quantity of infrastructure and summarise information about transport, communication and energy supply infrastructure (Box 4). There have been substantial increases in infrastructure capital over the period in all OECD countries. By the year 2000, the Nordic countries, the United States, Canada, Australia and other small European countries, such as Switzerland and, to a lesser extent, Ireland had the highest levels of infrastructure. New OECD members and transition NScountries, such as Mexico, Turkey, Poland and to a lesser extent Hungary, the Czech Republic and Korea, were estimated to have relatively low levels of infrastructure.

The provision of infrastructure may affect comparative and absolute advantage and, therefore, cross-country patterns of trade and FDI (Findlay, 1996). Infrastructure is likely to be particularly important for trade in services, because the main items traded (travel, freight, communications, banking and business services) depend heavily on the existence of high capacity and efficient networks in

Figure 18. **Infrastructure endowments<sup>1</sup>**  
United States 1998 = 100

1. The indicator is the crossing of the quality and quantity of infrastructure in transport, telecommunications and electricity. It increases with infrastructure endowments and is expressed relative to the 1998 level of the indicator in the United States.

Source: OECD.

**Box 4. Infrastructure indicators**

The infrastructure indicator summarises, on a 0-1 scale, the quality and quantity of telecommunications, transport and electricity infrastructure. Items covered include mainlines per capita, mobile phones per capita, the share of digital lines in total lines, answer seizure ratios (*e.g.* the percentage of successful international phone calls) and fault rates (*e.g.* the percentage of faults repaired within 24 hours) in telecommunications; length of motorways per capita, length of paved roads per capita and aircraft departures per capita in transport; transmission losses, generating capacity per capita and reserve margins in electricity supply. The relevant data were drawn from the OECD, the European Conference of Ministry of Transportation, International Energy Agency and World Bank sources. Each sectoral indicator is a weighted average of the corresponding items. The overall infrastructure indicator is a weighted average of the three sectoral indicators. Weights assigned to items and sectors reflect judgements about the economic relevance of each component. A time-series of the indicator was calculated for the 1980-2000 period.

countries that are at both ends of the transaction. Thus, the combination of infrastructure conditions in the exporter and importer countries is likely to be relevant for services trade, much in the same way as for product-market regulation (see above). The availability and the quality of infrastructure may also positively affect inward FDI because good infrastructure lowers transactions costs, facilitating international specialisation and the location choices of footloose industries (Jones, 2000).<sup>35</sup> However, a possible complication is that FDI in infrastructure has increased in recent years. Thus, it is possible that countries with weaker infrastructure might attract FDI, implying a reverse relationship between FDI and infrastructure endowments.

**Geographical and economic factors**

As already mentioned, a number of factors unrelated to government policies can impinge on trade and FDI. Gravity factors are mainly related to market size and distance: the volume of transactions between two countries tends to increase as their incomes get larger, but decreases with the distance between them due to transport costs.<sup>36</sup> Total and relative market sizes are also important determinants of horizontal FDI, because the returns from such investment depend on economies of scale at the firm level (see Box 2). On the other hand, factor proportions are important because they determine each country's comparative advantage in trading goods and services, and also affect the extent to which vertical FDI is

implemented.<sup>37</sup> In general, geographical and economic factors are expected to affect trade and FDI in the following ways:

- Exports and outward FDI both tend to be positively affected by the combined market size of the countries involved in the transactions, due to both gravity effects and economies of scale.
- Exports and *horizontal* outward FDI also tend to be positively affected by the size similarity of the two countries. Size similarity stimulates intra-industry trade and favours firm-level economies of scale of horizontal MNEs, which have multiple production plants at home and abroad producing the same good (or service) (see Markusen, 2002).
- Exports tend to be negatively affected by distance and transport costs. However, their effects on FDI are unclear because they also imply transaction costs for investors, and these costs could offset any advantage that FDI may have over trade when dealing with distant and ill-connected countries.<sup>38</sup>
- Exports tend to be stimulated by differences in factor endowments of trading partners, because these make it possible to exploit comparative advantages. For broadly the same reason, dissimilarities in factor endowments also encourage vertical FDI. Conversely, horizontal FDI is discouraged by factor dissimilarities because they may make production of the same good in different countries difficult.

## EMPIRICAL EVIDENCE

This section presents evidence on the impact of policy and other factors on bilateral outward FDI positions (henceforth FDI outstocks), multilateral inward FDI positions (henceforth total FDI instocks), bilateral exports of goods and bilateral exports of services of OECD countries. Thus, the focus is on the determinants of exports or outward FDI from a country to its partners and the determinants of the global attractiveness of a country for international investors. For ease of exposition, only the results from “preferred” regression specifications are reported below (for detailed results, see Nicoletti *et al.*, 2003). It should be noted at the outset that, due to limitations in data coverage, the data sets on which the results are based vary across the dependent variables and the policies considered. FDI outstock and instocks as well as goods exports cover 28 OECD countries and partners over the 1980-2000 period at the bilateral and multilateral levels. However, a long enough time-series of total FDI instocks is only available for a smaller set of OECD countries. Bilateral exports of services cover 20 reporting countries and

27 partners over the 1999-2000 period. All trade and FDI variables are expressed in dollars at 1996 purchasing power parity values.<sup>39</sup>

## Approach

The estimated equations are reduced forms relating trade in goods, trade in services and FDI outstocks to broadly the same set of factors. This is in line with recent research that stresses the joint determination of trade and FDI transactions.<sup>40</sup> Bilateral exports and outward FDI from the home country to the partner country (henceforth partner for brevity) were related to i) geographic and non-policy-related structural factors, and ii) the relative costs of trading and investing implied by policies in the home country or partner. FDI regressions focus on bilateral outstocks and multilateral instocks; results for bilateral outflows are broadly the same.<sup>41</sup>

Thus, the building blocks of the estimated equations are *geographical and non-policy-related structural factors* including:

- *Variables expressing gravity forces*: total GDP (the sum of home country and partner GDPs in bilateral equations) proxying for total market size; an index of similarity of GDPs proxying for size similarity; distance (from capitals); and transport costs (computed as the difference between CIF imports in the partner and FOB exports by the home country).<sup>42</sup>
- *Variables expressing factor proportions*: dissimilarity in capital-labour ratios; and dissimilarity in human capital endowments (taking into account the share of population by different education levels and average years of schooling in each level).
- *Other economic variables likely to affect trade or FDI*: R&D intensity in the home country or partner, defined as the ratio of business R&D expenditure to GDP; bilateral exchange rates, defined as nominal exchange rates in bilateral equations and effective (import-weighted) nominal exchange rates in total instock equations; and exchange rate variability, defined as the standard error of the monthly exchange rates.<sup>43</sup>

As in the previous section, *policy factors* are grouped in four categories:

- *Openness*: multilateral and bilateral tariffs; multilateral indicators of non-tariff barriers; dummies for free-trade agreements (henceforth FTA); and the indicator of FDI restrictions described in Golub (2003).
- *Product-market regulation*: this covers two broad areas – protection of intellectual property rights (henceforth IPR) and regulations curbing competition. The former is proxied by the Ginarte and Park (1997) cross-section indicator of protection of IPR in 1997. Anti-competitive regulation is proxied in two different ways. FDI and trade in goods are related to a time-series indicator that combines barriers to entry in seven non-manufacturing industries over

the 1980-1998 period with economy-wide regulation in 1998. Trade in services is related to an indicator summarising barriers to entry in twelve non-manufacturing industries in 1998.

- *Labour-market arrangements*: the tax wedge on labour income; an indicator of employment protection legislation (EPL); and an indicator of the degree of centralisation and co-ordination of the bargaining regime. The latter two indicators are interacted to account for the possible influence of bargaining institutions on the costs implied by EPL (see above).
- *Infrastructure*: the indicator of infrastructure supply in transport, telecommunications and electricity.

All indicators are normalised and range from 0 to 100. The scale of all policy indicators is from least to most restrictive, except for the indicator of IPR which is increasing in the *lack of* protection. The infrastructure indicator is increasing in the quality and quantity of infrastructure. Details on all variables and indicators used in the regressions, including sources, definitions, methodologies, sensitivity analyses and a description of cross-country patterns are contained in Nicoletti *et al.* (2003).

The empirical estimates are based on panel regressions that take into account four different kinds of effects potentially unexplained by the above set of variables and indicators: *i*) time invariant effects that are specific to each home country and partner (*e.g.* institutions, data collection and reporting methods); *ii*) time invariant effects that are specific to each country pair involved in bilateral transactions (*e.g.* common language, cultural affinity); *iii*) time-varying factors common to all home countries and partners (*e.g.* global demand, supply or technology shocks); and *iv*) time-varying factors specific to each home country and partner (*e.g.* business cycle, country-specific technology shocks).<sup>44</sup> The econometric approach takes into account these factors either explicitly (by estimating the relevant parameters) or implicitly (by transforming the data prior to estimation) as in Erkel-Rousse and Mirza (2002).<sup>45</sup> In the analysis of bilateral trade or FDI, the observations are home country-partner pairs in each period; in the analysis of total FDI instocks observations are countries in each period. The analysis of total FDI instocks accounts for the possibility that the adjustment of actual to desired stocks of FDI is costly and takes time. Therefore, equations for total FDI instocks are of the dynamic partial adjustment kind, with the total FDI instock in each period also depending on the realised instock in the previous period (see Cheng and Kwan, 2000, for a similar specification). Moreover, the estimations also account for the possibility that some of the variables explaining FDI might be endogenous to outcomes (*e.g.* while the FDI instock may depend on infrastructure conditions in the country, infrastructure conditions themselves may depend on FDI in infrastructure) by using an appropriate instrumental variables estimation approach. Finally, the total instock equations also account for the possibility that investments in FTAs are the outcome of a two-stage

process in which, first, the decision is made to invest in the FTA, and, second, locations within the FTA are chosen based on the relative attractiveness of member countries.<sup>46</sup> Estimation methods are briefly summarised in Box 5.

All the results reported below are based on full-model specifications including both non-policy related variables and policy variables. However, the results are generally robust to the omission of subsets of policy variables. It is important to keep in mind that the results for the total FDI instock are based on a dynamic specification, which is significantly different from the static bilateral one, and covers a more limited set of countries.<sup>47</sup>

### **Non-policy-related structural factors impinging on trade and FDI**

Table 2 reports the estimates of the basic equations that include only non-policy-related structural factors. Four main features stand out:

- First, as expected, the coefficients of the gravity variables are correctly signed and significant in all equations. Thus, market size, market similarity, distance and transport costs affect in the same way FDI and exports of goods and services.<sup>48</sup>
- Second, the estimated effect of market size on trade in services and FDI is stronger than in goods trade, while the effect of transport costs (proxied by distance in the services trade equations) is smaller. While a smaller effect of transport costs on FDI is expected, because these should affect (indirectly) only vertical MNEs, the smaller effect on services is surprising, because such costs are often quoted as the reason for the lower intensity of trade in this sector. Thus, neither gravity nor transport cost factors seem able to explain the different trade intensities observed for goods and services.
- Third, the effects of differences in endowments of labour and physical or human capital vary across FDI, trade in goods and trade in services. Differences in endowments positively affect trade in goods, as would be expected from comparative advantage considerations. However, factor dissimilarities negatively affect outward FDI, though a high level of human capital tends to attract inward FDI. Taken together, the findings of a positive effect of market size similarity and a negative effect of factor dissimilarity support the conjecture that FDI by horizontal MNEs is prevalent among OECD countries. Finally, factor dissimilarities have no statistically significant impact on services trade. This finding may be interpreted as suggesting that the various kinds of services respond unevenly to those differences (*e.g.* while comparative advantage factors could sometimes be playing a positive role in tourism, similarity in endowments could be needed in financial or communication transactions).

### Box 5. Empirical methods

Regression results are obtained from single-equation estimation of reduced forms for bilateral FDI outstocks, goods exports and service exports as well as for total FDI instocks. To appropriately account for both the cross-section and time-series dimensions of the data, panel data estimation methods are used.

In bilateral equations, panel data methods require controlling for unobserved factors that are specific to each country, each partner, each country-partner pair and each period, as well as for shocks that are common to all countries over time. However, estimating dummies for all these factors is not viable, due to an excessive loss of degrees of freedom. Therefore, the “transformed least squares” (TLS) approach (Erkel-Rousse and Mirza, 2002) was employed, which simplifies the equation to be estimated while at the same time preserving the desirable properties of the relevant coefficient estimates. This approach expresses all variables as deviations from the mean investor (or exporter) or, alternatively, the mean host (or importer). Thus, for instance, two equations for bilateral FDI outstocks are obtained: a “country” equation, in which bilateral outstocks and all explanatory variables are expressed as deviations from their values for the average investor; and a “partner” equation, in which bilateral outstocks and all explanatory variables are expressed as deviations from their values for the average host. The advantage is that in the country equations partner-specific unobserved effects (and common time trends) are accounted for prior to estimation in a non-parametric way and only country-specific effects have to be estimated, while in the partner equations it is the country-specific unobserved effects (and common time trends) that are accounted for non-parametrically and the partner-specific effects that are estimated. This reduces the number of parameters to be estimated in each equation.\* The downside is that, due to the transformation of the data, no time-invariant partner-specific variables can be included in the country equations and, symmetrically, no time-invariant country-specific variables can be included in the partner equations. Finally, additional degrees of freedom are gained by assuming that, in each of the two equations, the incremental information provided by the unobserved country pair effect over the “pure” country or partner effect is random and can be included in the error term.

Total instock equations are estimated using a panel data procedure that controls for the possible inconsistency of estimates implied by the presence of the lagged dependent variable and the potential endogeneity of some of the explanatory variables (Bond, 2002). To this end, the equations are first-differenced, the lagged dependent variable and endogenous explanatory variables are instrumented by the lagged values of the variables themselves and the parameters are estimated applying a generalised method of moments procedure (Arellano and Bond, 1991). Serial correlation tests and Sargan tests for over-identifying restrictions were performed to ensure that the regression specifications reported in the main text were supported by the data.

\* To check the robustness of regression results to this transformation, each equation was also estimated using a standard fixed effects regression, including all unobserved effects save the country-partner pair effects.

Table 2. Non-policy-related structural factors impinging on trade and FDI

Dependent variable (ln)	Export of:				FDI

- Equations estimated using the Transformed Least Squares (TLS) approach (Erkel-Rousse and Mirza, 2002). "Country" indicates the use of data expressed as deviations from the mean host that allows for estimation of investor-specific variables, "partner" indicates the use of data expressed as deviations from the mean investor that allows for estimation of host-specific variables.
- The dynamic panel specification was estimated using the Arellano and Bond (1991) generalized method of moments estimator.
- Defined as domestic absorption in the total instock regressions.
- Coefficients multiplied by 100.
- Samples are adjusted for outliers based on the Welsch distance cut-off (Chatterjee and Hadi, 1988).
- The R-squared is reported only in fixed effects regressions.
- The Sargan statistic tests the null hypothesis that all moment conditions are satisfied. The statistic is  $\chi^2$ -distributed with degrees of freedom in parenthesis.
- These tests check the assumption that residuals are serially uncorrelated. This assumption implies that their first differences follow an MA(1) process having non-zero first-order correlation but no higher-order correlation. Reported statistics, both distributed  $N(0,1)$ , test the null hypothesis of zero first-order and second-order autocorrelation, respectively.

Source: OECD.

- Fourth, the sizeable coefficient estimate for the lagged FDI instock in the dynamic total instock regressions suggests that there is a high persistence present in the data, with FDI flowing to countries that already have relatively high bilateral instocks. This phenomenon may reflect the presence of “agglomeration effects”, whereby FDI is attracted to locations in which important investments by home country MNEs have already been made (see, for related evidence, Barrell and Pain, 1998 and 1999).<sup>49</sup>

R&D intensity in the home and partner countries and the level and volatility of bilateral and effective exchange rates have the expected influence on trade and FDI. R&D in the home country is a common proxy for product differentiation, which positively affects intra-industry trade. At the same time, the overall level of R&D expenditure in the host country increases its attractiveness for total inward FDI. For given relative prices (whose effect is captured by relative factor endowments and, in later regressions, by the product and labour-market regulation variables), an exchange rate appreciation curbs the competitiveness of home country exports of goods, as pointed out by the negative and significant estimates of its coefficient in bilateral export equations. However, it has two opposing effects on FDI. On the one hand, it reflects a pure valuation effect, with the US\$ value of assets held by the home country in the host country decreasing; on the other hand, it reflects an asset effect, increasing the attractiveness of investment in the host country, as its assets become cheaper for foreigners. The results are ambiguous. The estimated effects change sign across bilateral FDI specifications, though the valuation effect seems to prevail in most regressions (see Nicoletti *et al*, 2003). At the multilateral level (as captured by the dynamic total instock regressions), the asset effect seems to prevail, perhaps due to composition effects.<sup>50</sup> The effects of exchange rate variability are discussed below.

### The direct and indirect influence of policies

Table 3 reports the results of regressions that include policy variables. The reported specifications generally include all of them. However, some policy variables are sometimes omitted when the inclusion of all variables would imply either significant changes in country coverage (such as in the total instock equations) or excessive multicollinearity (such as in the cross-section services trade regressions). Most of the variables are expressed in ratios, but country or partner-specific policy variables in trade equations are expressed in level terms in line with trade literature (*e.g.* Helpman and Krugman, 1995). To highlight similarities and differences in the way policies may influence trade in goods, trade in services and bilateral or multilateral FDI, it is useful to look at the estimated effects of each policy across the different measures of trade and FDI. Therefore, the effects of each of the four sets of policies covered in this paper are analysed in turn under the usual headings.

## Openness

FDI restrictions by the partner are estimated to have a significant negative impact on bilateral FDI outstocks (Table 3, Panel A). For instance, the semi-elasticity estimates imply that such barriers could be depressing FDI outstocks by between 10 and 80 per cent, depending on the restriction considered (see Table 4).<sup>51</sup> FDI restrictions are also found to significantly depress the inward position of a host country in the dynamic total instock regressions, which are based on a smaller set of OECD countries. However, this effect appears to be sensitive to changes in the country coverage, probably due to a relative lack of variability of restrictions across subsets of OECD countries, and to the inclusion of additional policy variables in the regression, reflecting the close correlation between FDI and product-market liberalisation over the sample period.

Similarly, border barriers directly affect trade in goods (Table 3, Panel B). Applied bilateral tariff rates have a significant negative effect on exports, with the estimated elasticities implying around 1 per cent increase in exports as tariffs decline by 1 percentage point. Moreover, the estimates suggest that a decrease by 1 percentage point of the import coverage of (multilateral) non-tariff barriers in the partner may also increase bilateral exports of the home country by around 1 per cent. These results should be interpreted with caution because, due to data limitations, both the tariff and non-tariff measures are not fully appropriate: applied bilateral tariffs are available for only one recent year, and cover therefore only the cross-section dimension, while the available non-tariff measures are multilateral, and therefore do not accurately account for the influence of border barriers on bilateral trade.<sup>52</sup>

Table 3 also reports estimates of the potential cross-effects of border barriers on trade and FDI. To this end, tariff and non-tariff barriers were included in the FDI equations (to test for the tariff-jumping hypothesis) and, conversely, FDI restrictions were included in the trade equations. Estimation results for bilateral FDI outstocks and, especially, total instock equations provide some evidence that FDI may be aimed at bypassing non-tariff barriers, which often establish limits to market access (*e.g.* quotas), rather than tariff barriers, which generally add to the cost of trade without necessarily foreclosing exports. Indeed, tariff barriers appear to have a negative effect on FDI outstocks, perhaps reflecting their discouraging effect on the intra-firm trade related to vertical FDI. Some evidence of cross-effects is also found in services trade equations, with FDI restrictions negatively affecting trade in some regressions, perhaps reflecting the complementarity between commercial presence and consumption abroad or cross-border supply for some services (*e.g.* tourism). Cross effects are not found for exports of goods, suggesting that goods trade is not frequently resorted to as a means of bypassing FDI restrictions.

As regards FTAs, the empirical analysis considered the impact of different situations of the home and partner countries: *i*) the two countries belong to *any* FTA;

ii) the partner belongs to *any* FTA; iii) the two countries belong to the *same* FTA; iv) the two countries belong to the EU, NAFTA or EFTA; and v) the partner (but not the home country) belongs to the EU, NAFTA or EFTA. Only results concerning the latter three situations and, for services trade regressions, membership in the EU or NAFTA are reported, since the dummies for membership of both countries or the partner in any FTA were insignificant in most cases. The analysis of situations iv) and v) omitted policy variables unrelated to openness to avoid multicollinearity problems, but the results are broadly unchanged in specifications including all policy variables. The three main findings were:

1. Membership in the *same* FTA increases both exports of goods and FDI outstocks (Table 3);
2. Bilateral exports of goods and outward FDI to partners belonging to a different FTA tend to increase only when the partner is a EU country (Table 5);
3. The effect of FTA membership on exports of services is insignificant. In particular, close integration under the Single Market Programme does not appear to have boosted services trade among EU countries (Table 5).

Thus, FTAs that eliminate border barriers appear to be unsuccessful in raising services trade, perhaps because the latter is often impeded by non-border barriers.

Table 4. **FDI positions: the hypothetical effect of removing FDI restrictions<sup>1</sup>**  
Average across countries

	Per cent change in inward FDI position
Removal of foreign equity ceilings	77.9
Removal of approval and national interest tests	21.2
Easing of nationality requirements on management <sup>2</sup>	10.1

1. The simulations are based on coefficients estimated in panel regressions of bilateral outward FDI positions on non-policy factors (distance, transport costs, market size, similarity in size and factor endowments, and other country and time-specific effects) and policy influences (FDI restrictions, tariff and non-tariff barriers, participation in free trade areas, and product and labour market arrangements). The regressions cover bilateral FDI relationships between 28 OECD countries over the 1980-2000 period.

2. From majority of domestic managers to only one or more domestic managers.

Source: OECD.

Moreover, FTAs appear to benefit principally goods trade among their members, but have little impact on trade with third-party countries (independent of their membership in another FTA), except when trading with a EU member. While FTAs also benefit FDI among their members, FDI outstocks are stimulated as well when the partner belongs to the European Union, though this effect is only weakly significant. In other words, the European Union appears to be more attractive for third-party FDI and exports than other FTAs, such as NAFTA. This may be related to lower average tariffs, closer integration (*i.e.* a custom union *versus* a free-trade area) in the Single Market and/or the different role played by rules of origin in the two areas.<sup>53</sup>

Exchange rate variability can be interpreted as capturing the effect of economic unions to the extent that these generally require stable exchange rate arrangements or a single currency. In most regressions, a reduction of both bilateral and multilateral exchange rate volatility tends to increase FDI in the host country. Though this effect is not significant at conventional levels in the regressions reported in Tables 3 and 5, it is significant in other bilateral and multilateral specifications of the FDI outstock and outflow equations (see Nicoletti *et al.*, 2003). In some specifications, however, the sign is reversed, suggesting a positive relationship between exchange rate volatility and FDI, and no effects of volatility could be found on goods or services exports (the variable was therefore omitted from the preferred bilateral trade specifications reported in the tables). Whether currency unions stimulate economic integration among their members remains, therefore, a largely unresolved empirical issue.

### **Product-market regulation**

Product-market regulations that curb competition are estimated to have a negative and significant effect on both trade and FDI (Table 3). However, the results suggest that they do so in different ways for FDI, trade in goods and trade

in services. What is relevant for bilateral FDI outstocks is the ratio of the regulatory indicators in the host and home countries. As regulation in the host country becomes more restrictive than regulation in the home country, outstocks of the latter decrease. This is confirmed by the significantly negative impact of anti-competitive regulations in the host country (relative to the OECD average) on its total FDI instock.<sup>54</sup> Put simply, the net effect of regulations that curb competition is to make the host country less attractive for international investors located in countries where regulations are less restrictive. No robust effect of the lack of intellectual property rights protection in the host country could be found on FDI outstocks, perhaps due to the crude proxy used to test for this potential effect of policies, which varies only in the cross-section dimension.<sup>55</sup> Hence, this variable was omitted from the preferred specifications reported in Table 3.

Conversely, what is most relevant for bilateral exports of goods is the level of regulation in the home country, which increases production costs, curbing the competitiveness of exports, distorts relative prices and possibly reduces also opportunities for intra-industry trade by narrowing product variety. To a lesser extent, regulations in the partner countries also tend to depress exports, suggesting that their effect on market access dominates the possible stimulating effect on the competitiveness of foreign *versus* home goods.

Finally, estimation results point to an identical effect of regulations in the home and the partner country on bilateral services exports. In other words, statistical tests suggest that it is the *product* of the regulatory indicators in the two countries that has a negative and significant effect on services trade. This probably reflects the need for using efficiently inputs in both countries to produce many of the services that are traded (*e.g.* travel, freight, tourism, communication, banking). Moreover, regulation is estimated to have a stronger impact on services trade, as measured by the size of the estimated coefficient, than on both goods trade and FDI. The fact that anti-competitive regulations are generally more widespread in services, that these regulations combine in both the exporter and importer countries to lower service exports and that their combined impact is stronger than in goods trade, could contribute to explain not only cross-country patterns of services trade but also observed differences in trade intensities of goods and services.

### **Labour-market arrangements**

The tax wedge on labour income appears to influence FDI in much the same way as anti-competitive regulation. What appears to be relevant for bilateral FDI outstocks is the ratio between wedges in the partner and the home country: the higher this ratio, the lower the outstock of FDI from the home country to the partner. This latter result is only partially confirmed by the dynamic total instock estimates, in which the wedge is estimated to have a negative, but weakly significant,

impact on the ability of the host country to attract OECD-wide FDI. As with product-market regulation, bilateral exports of goods are significantly depressed by a high tax wedge in the home country, suggesting that its impact on production costs is not fully offset by wages. In this case, however, a symmetric (though weaker) reverse effect is found for a high tax wedge in the partner, which *ceteris paribus* raises the competitiveness of the home country exports. Finally, high tax wedges in both the home country and the partner are estimated to have depressing effects on bilateral service exports, confirming that traded services may use labour inputs in both countries involved in the transaction.<sup>56</sup>

Results for EPL are similar but more nuanced, because some of them depend on the bargaining regime in place in the home country and the partner. The effect of EPL on bilateral FDI outstocks and total FDI instocks mirrors that of anti-competitive regulations and wedges: host countries in which EPL is stricter than in their investing partners tend to attract significantly less FDI. Here, the bargaining regime plays no moderating role, perhaps due to the influence of EPL regimes on the risk-adjusted returns to foreign investment or differential information costs for domestic and foreign investors (see above). On the other hand, strict EPL in the home country depresses goods exports by increasing production costs, thus curbing the competitiveness of exported goods, and distorting relative prices, but only in countries where industry-level bargaining (labelled “mid-level corporatism” in Table 3) discourages the shift of those costs to wages. At the same time, no effect of strict EPL in the partner is found, independent of the level of corporatism.

Finally, in services trade strict EPL in the home country and the partner both have a negative effect on exports, further confirming the pattern already observed for regulation and wedges. However, this effect vanishes in highly corporatist home countries.

### **Infrastructure**

Table 3 looks only at the influence of infrastructure provision on FDI and trade in services, because the role of infrastructure for trade in goods is indirectly captured by transport costs and, therefore, is not modelled explicitly.<sup>57</sup> Even though the coefficient estimated for infrastructure has the expected sign, the estimation results provide little evidence that the quality and quantity of infrastructure in the partner, as captured by the indicator described in the previous section, significantly affects bilateral patterns of FDI. Therefore, this variable was omitted from the “preferred” specifications reported in Table 3. The lack of any definite result for this variable may also be related to its potential endogeneity to FDI (see above). Indeed, total instock regressions, which control for endogeneity through instrumental variable estimation, suggest that infrastructure tends to improve the overall attractiveness of a host country for international investors, though this result is sensitive to changes in country coverage.<sup>58</sup> Moreover, transport infrastructure is estimated to have a sizeable and significant positive effect on trade in services. Here, infrastructure in both the country and partner is relevant for trade and, therefore, transport infrastructure is defined as the product of the indicator values in the two countries.<sup>59</sup> The results suggest that the elasticity of bilateral service exports with respect to transport infrastructure provides a significant offset to the negative effect of distance. Poor or inefficient infrastructure is therefore a supplementary explanation of both cross-country services trade patterns and the relatively low trade intensity observed in the service sector.

### **Summing up**

Empirical results broadly support the influences expected from both non-policy related and policy factors on trade and FDI. The main insights are the following:

- Gravity forces affect trade and FDI in the same way. However, the effect of market size and transport costs on FDI and trade in services is, respectively, stronger and weaker than in goods trade. Thus, economic and geographic considerations alone are unable to explain the significant difference in the intensity of trade in goods and services.
- Border barriers have a direct depressing effect on both trade and FDI, but there is also evidence that MNEs may be able to bypass non-tariff barriers, which limit the access of exporters to local markets, by increasing the activity of their foreign affiliates in these markets. Conversely, no such bypass

seems to occur for tariff barriers, which raise the cost of trade for both exporters and vertical MNEs.

- Participation in a FTA enhances trade and FDI amongst its members, but the only FTA that appears to have benefited also from an increase in trade and FDI from third parties is the European Union, perhaps due to its closer degree of integration. Moreover, FTAs do not appear to have affected positively services trade among their members, which might be due to limited coverage of the agreements and remaining non-border barriers.
- There is some evidence that the supply of high quality infrastructure enhances the overall appeal of a host country with respect to inward FDI. Moreover, good infrastructure conditions in both the home country and partner have a powerful positive effect on services exports.
- Anti-competitive regulations curb FDI and trade, with a particularly strong negative effect on services trade, which is sensitive to regulatory conditions in both the home country and the partner.
- High tax wedges on labour income and strict EPL also curb FDI and trade, but the effect of EPL on trade depends on the bargaining regime. Again, services trade is particularly sensitive to conditions in both the home country and the partner.
- Taken together, the results for services trade suggest that poor or inefficient infrastructure, lack of competitive pressures and adverse labour-market arrangements in trading partners could contribute to explain the low services trade intensities relative to goods trade observed in many OECD countries.

## HOW DO POLICIES SHAPE TRADE AND FDI PATTERNS?

The impact of policies on trade and FDI is significant, but how much of the observed differences in bilateral trade and FDI transactions among OECD countries can actually be explained by differences in policies? What are the policies that play the largest role in explaining such differences? What would be the effect of changing policies on trade and FDI? Bearing in mind the illustrative nature of any policy simulation based on regression results, empirical estimates can be used to provide tentative answers to these questions.<sup>60</sup> Specifically, this section quantifies *i*) the relative contributions of policies and other factors to the observed deviations of exports (of goods and services) and FDI from OECD averages; and *ii*) the long-run impact on total FDI instocks and export flows of changes in policies that affect border barriers, labour taxation and product-market regulation. It is important to notice that the quantitative effects highlighted in the policy

simulations depend on the specification of the estimated models as well as on the configuration of policies and the distribution of FDI stocks and trade flows in the baseline scenario. This is particularly the case for simulations concerning domestic regulatory policies in product and labour markets. Finally, given the specification of some of the policy variables, which entail a comparison between policies of the home country and the partner, diversion effects are not taken into account. To the extent that these effects are important, the simulation results may overestimate the effects of policy changes on the variables of interest.

### Accounting for cross-country patterns of trade and FDI

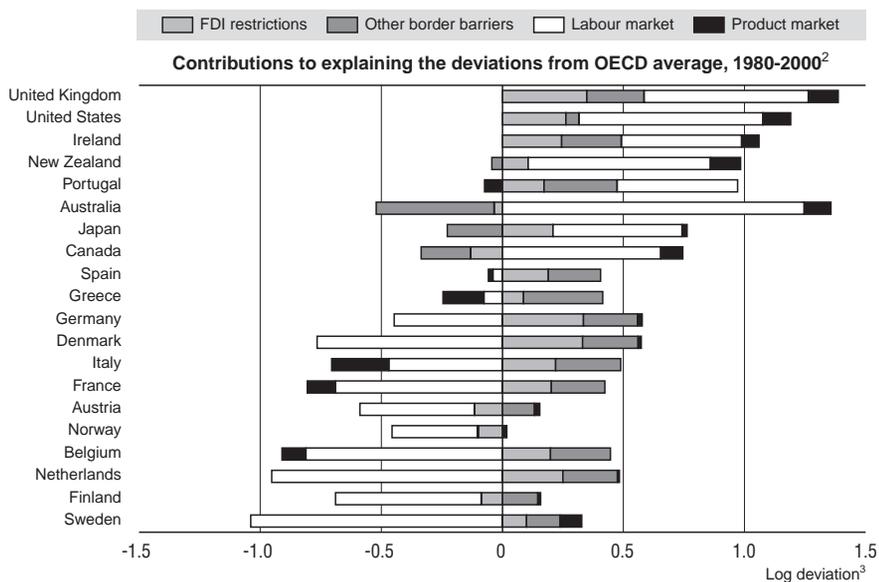

Figures 19-21 show the contributions of policies to the deviation (in logarithms) of total FDI in stocks, services exports and goods exports in each country from the OECD average over the 1990s. The figures also show how much of these deviations is explained on average by non-policy-related factors – including gravity forces, factor endowments and all effects that are not accounted for by the policy and non-policy-related variables in the regressions (*i.e.* the country and partner-specific fixed effects and the bilateral effects) – and the unexplained regression residual.<sup>61</sup> The decompositions shown in the figures are based on the results of the bilateral equations averaged over the estimation period and investor countries (for FDI in stocks) or importer countries (for exports of goods and services). The precise specifications on which the simulations are based are reported in the figures.

Policies influence bilateral FDI positions across member countries almost as much as all other (“non-policy”) factors taken together (Figure 19).<sup>62</sup> The most important policy effects come from labour-market arrangements and openness factors. A more detailed analysis shows that the labour tax wedge is the most influential component of these arrangements, with EPL playing a lesser role. Anti-competitive product-market regulations explain a smaller part of the deviations of FDI in stocks from the OECD average. However, these policy influences play different roles in different countries. For instance, while labour-market arrangements have a relatively positive influence on FDI in stocks in English-speaking countries, Japan and Portugal, they tend to depress them in other European countries. Similarly, while in most European countries and the United States openness factors play a positive role, comparatively restrictive border measures depress FDI in stocks relative to the OECD average in Canada, Australia and, to a lesser extent, Japan. The contribution of product-market regulation is significant for countries having either a relatively liberal approach (the United States, the United Kingdom, Australia, New Zealand, Canada and Sweden), where it pushes up relative FDI in stocks, or a relatively restrictive approach (continental European countries), where it pulls down relative FDI in stocks.

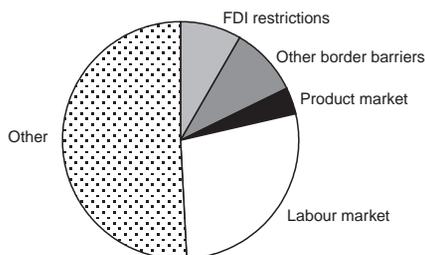

Policies also play an important (though smaller) role in explaining why services exports are above or below the OECD average (Figure 20). In this case, the

contribution of other factors is inflated by unexplained regression residuals, which are larger than for FDI. The contribution of policies to explaining services trade is more evenly distributed than for FDI among product-market regulation, the tax wedge, and infrastructure provision though the latter tends to predominate. The tax wedge favours services exports relative to the OECD average particularly in Australia, Japan, Portugal, the United Kingdom and the United States, while it penalises them in France, Austria, Finland, Denmark and, especially, Sweden. Having comparatively liberal product markets in services industries enhances services exports relative to the OECD average in the United Kingdom, Australia, Sweden, Finland and the United States, while relatively restrictive markets curb them in Canada, Greece, Portugal and Austria. Finally, relatively poor transport infrastructure endowments depress services exports in Japan and Italy, while its effect is either positive or close to zero in other countries.

Policies can explain only a relatively small part of the cross-country variance in goods exports (Figure 21). Most of this variance is explained by geographical and other non-policy-related factors (such as market size and distance from major OECD markets). The main policy influences come from bilateral openness (*e.g.* the border barriers faced by the exporter country when trading with its partners) and labour-market arrangements, while product-market regulations generally play a lesser role. Exports of EU countries are pushed up relative to the OECD average by bilateral openness with trading partners, which are mainly within the Single Market, while non-EU countries suffer from a relative lack of bilateral openness with respect to their EU trade partners. A closer look at the impact of policies in each country suggests that, in many cases, offsetting effects are at work. For instance, Australia, New Zealand, the United States, Canada and Japan are penalised by a relative lack of bilateral openness, but relatively liberal labour and/or product-market policies help to offset this negative bilateral openness. Conversely, while goods exports in European countries are stimulated by gravity factors, they are negatively affected by a relatively restrictive policy stance in labour and product markets. The only countries in which all policy factors depress goods exports relative to the OECD average are Switzerland and, to a lesser extent, Norway.

### **The impact of removing impediments to trade and FDI**

The lifting of border and non-border barriers to trade and investment figures significantly on both national and international policy agendas (see, for instance, World Bank, 2002, 2003; and OECD, 2001d, 2003). To quantify the likely impact of such policy changes, the preferred equations described above have been used to simulate the following hypothetical policy scenarios:

- *Policies aimed at lifting border barriers.* These include i) the OECD-wide alignment of FDI restrictions and multilateral non-tariff barriers on those of the

least restrictive OECD country; ii) the alignment of bilateral tariff rates on those of the least restrictive trading partner or the least restrictive country pair; and iii) the accession to the European Union by the Czech Republic, Hungary and Poland;

- *Domestic competition-oriented policies in product markets* that result in an alignment of product-market regulations on those of the least restrictive OECD country;
- *Domestic labour tax reforms* that result in the alignment of the labour tax wedge on that of the OECD country with the lowest wedge.

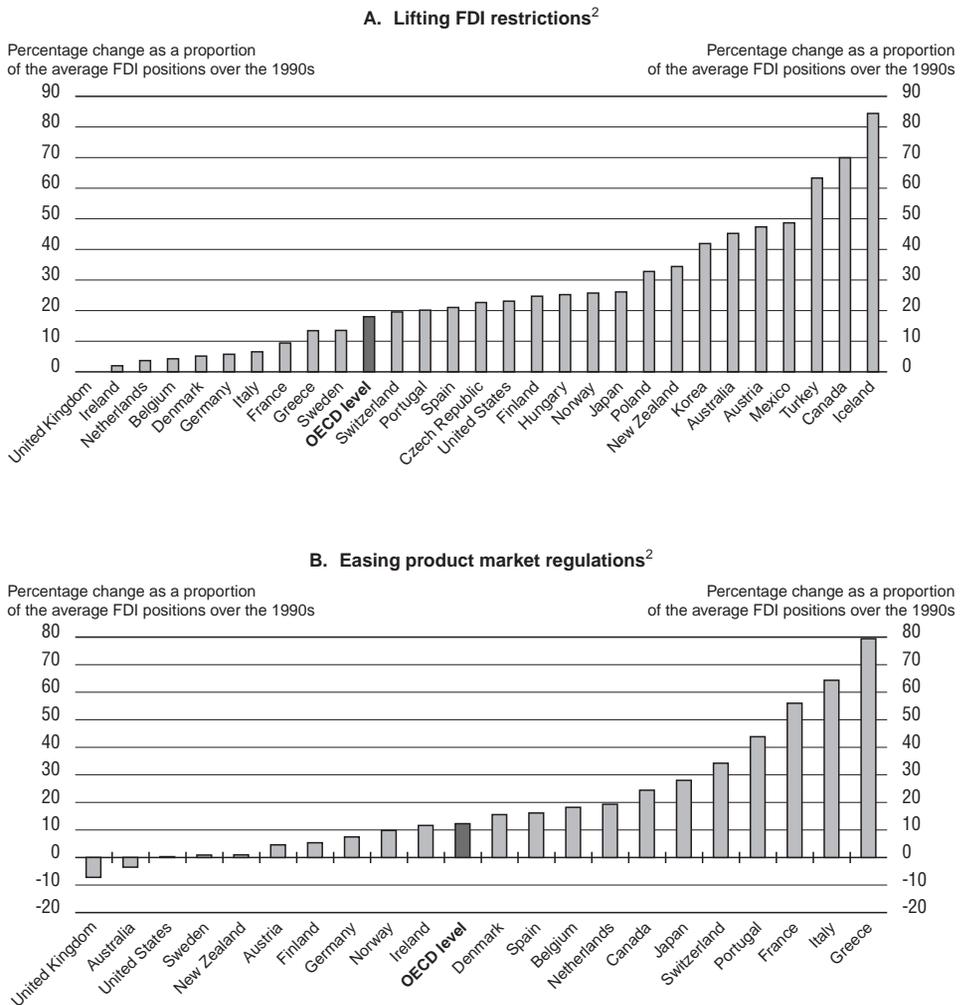

### **Policies and FDI**

Figure 22 (Panel A) shows the effect of bringing FDI restrictions in all OECD countries down to the level of restrictions in the United Kingdom, the least restrictive country according to the indicator described in Golub (2003). This move would require country-specific reforms that differ in content and scope depending on the patterns of FDI restrictions in place, but typically they would imply lifting screening requirements and restrictions on foreign shareholdings, and substantially reducing other restrictions (*e.g.* on the nationality of management, board composition and movement of people). The effects of such reforms on FDI instocks depend on how restrictive each country was before the policy move. Relatively restrictive countries could increase their total FDI instock by between 40 and 80 per cent, but even in countries that are estimated to be already relatively liberal the gains could amount to around 20 per cent of their initial instock.<sup>63</sup> Overall, such policy reforms could increase OECD-wide instocks by almost 20 per cent.

Reducing anti-competitive product-market regulations is also likely to increase significantly FDI instocks (Figure 22, Panel B). If all OECD countries were to reduce the level of their product-market regulations to that in the United Kingdom (the least restrictive country), OECD-wide instocks would increase by over 10 per cent relative to the initial instock. Since bilateral FDI outstocks are estimated to depend on the relative stringency of regulation in the home and host countries, relatively restrictive host countries – such as Greece, Italy and France – that host FDI from relatively liberal countries could increase their FDI instocks by as much as 60 to 80 per cent through regulatory reform. Conversely, countries that are relatively liberal would see the relative attractiveness of their product markets either unchanged (such as in the United States, New Zealand and Sweden) or even reduced (such as in the United Kingdom and Australia).

### **Policies and trade**

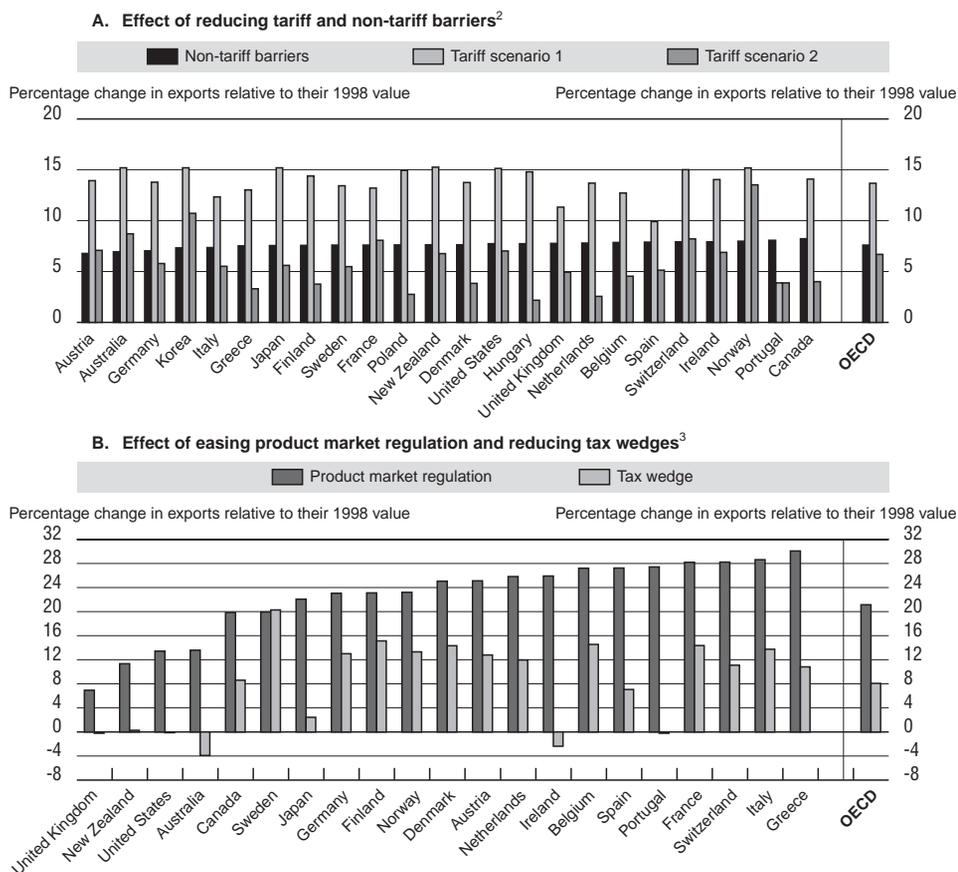

Figure 23 looks at the effects of three different policies – reducing tariff and non-tariff barriers (panel A), liberalising product markets and reducing the tax wedge on labour income (panel B) – on country-specific and OECD-wide goods

Figure 22. Policies and inward FDI positions: the scope for further integration<sup>1</sup>

1. The simulations are based on coefficients estimated in panel regressions of bilateral outward FDI positions on non-policy factors (distance, transport costs, market size, similarity in size and factor endowments, and other country and time-specific effects) and policy influences (FDI restrictions, tariff and non-tariff barriers, participation in free trade areas, and product and labour market arrangements). The regressions cover bilateral FDI relationships between 28 OECD countries over the 1980-2000 period.

Figure 23. **Change in goods exports from reducing tariff and non-tariff barriers, product-market regulation and the tax wedge on labour income<sup>1</sup>**

1. The simulations are based on coefficients estimated in panel regressions of bilateral outward FDI positions on non-policy factors (distance, transport costs, market size, similarity in size and factor endowments, and other country and time-specific effects) and policy influences (FDI restrictions, tariff and non-tariff barriers, participation in free trade areas, and product and labour market arrangements). The regressions cover bilateral FDI relationships between 28 OECD countries over the 1980-2000 period.
2. *Tariff scenario 1*: bilateral tariffs are reduced to the least restrictive average bilateral tariff in the OECD (0.057% in 2001). *Tariff scenario 2*: for each country bilateral tariffs are reduced to the least restrictive average tariff it faces when trading with its OECD partners in 2001. *Non-tariff scenario*: the import coverage of multilateral non-tariff barriers is aligned in all countries to that of the least restrictive country in 1996 (Iceland). For Iceland, simulations cannot be presented as this country is present in the sample only as a partner.
3. The simulation shows the effects of an easing of regulations in all countries to the level of the least restrictive country and a decrease in tax wedges to the level of the lowest wedge country in 2000 (Australia).

Source: OECD.

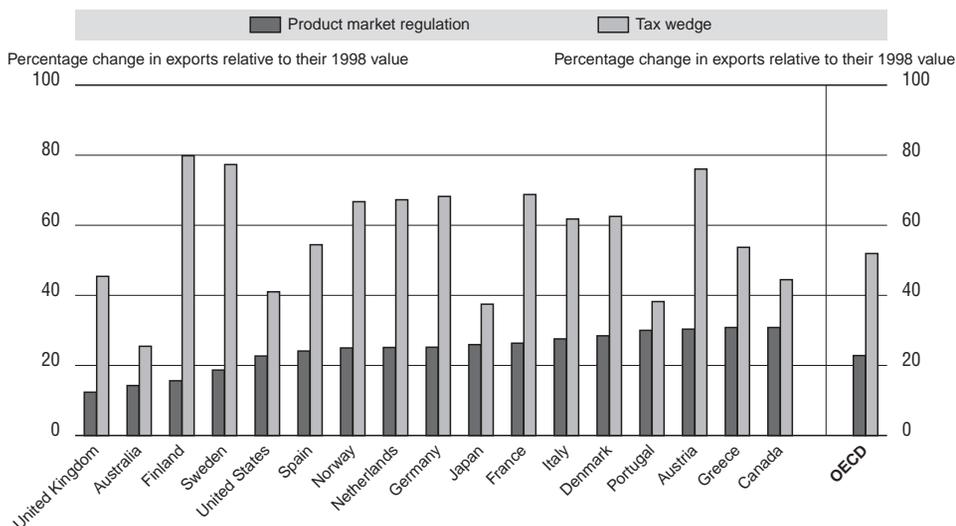

exports. Countries are ordered according to the cumulative gains obtained by implementing these policies. For bilateral tariffs, two scenarios are simulated: the decrease of tariffs to meet the lowest tariff among each country's trading partners; and the equalisation of all tariffs at the level of the lowest bilateral tariff observed in the OECD area. Consistent with regression results (see above), the liberalisation and labour tax reduction scenario take into account the cumulative effects on exports of policy changes in both the exporter and importer countries.

The increase in the level of total exports within the OECD area ranges from 6 to 20 per cent, depending on the policy package implemented. Unsurprisingly, the largest and most widespread gains are obtained by setting all bilateral tariffs to their minimum OECD level (close to zero), but significant large gains are also obtained when the import coverage of non-tariff barriers is reduced to the level found in the least restrictive country (Iceland according to the indicator presented above). Country-specific gains from these policies (relative to the level of exports in 1998) depend on the initial geographical distribution of a country's exports, but generally lie within a range of 10 to 15 per cent. The alignment of tariffs on those of the least restrictive partner would imply smaller gains (ranging from 4 to 10 per cent for most countries), partly because trade with high-tariff partners is usually weak. Simulated export gains from easing multilateral non-tariff barriers are more uniform across countries (around 7 to 8 per cent), partly reflecting the smaller cross-country differences due to the lack of the bilateral dimension in the available data.

Large OECD-wide gains are also obtained by aligning regulatory restrictions on those of the least regulated OECD country in 1998. The increase in exports implied by such policy for relatively restrictive countries – such as Greece, Portugal, Italy, France, Switzerland and Ireland – is about 30 per cent. Finally, curbing tax wedges to meet those of the lowest tax wedge country in 2000 (Australia) yields smaller, but still noticeable, OECD-wide gains. Indeed, in several European countries, where wedges are relatively high, this policy yields gains that are comparable to those obtained by reducing non-tariff barriers. Interestingly, the export losses implied by this policy scenario in a few countries (notably Australia and Ireland) reflect the relative loss in competitiveness of these countries' exports to countries that experience a large drop in the tax wedge as a result of the policy. On the whole, changes in policies have significant effects on goods exports in most countries, even though their absolute contribution to explaining deviations of exports from the OECD average is small (see above).

Figure 24 reports the results of a similar simulation for exports of services.<sup>64</sup> In this case, the gains implied by non-manufacturing product-market liberalisation and lower labour tax wedges are larger, reflecting the stronger estimated effect of policies on bilateral service exports. Tax and product-market reform could increase total services exports among OECD countries by 50 and 20 per cent, respectively.

Figure 24. **Change in services exports from easing product-market regulation and reducing the tax wedge on labour income<sup>1, 2</sup>**

1. The simulations are based on coefficients estimated in panel regressions of bilateral outward FDI positions on non-policy factors (distance, transport costs, market size, similarity in size and factor endowments, and other country and time-specific effects) and policy influences (FDI restrictions, tariff and non-tariff barriers, participation in free trade areas, and product and labour market arrangements). The regressions cover bilateral FDI relationships between 28 OECD countries over the 1980-2000 period.

### EU accession, FDI and trade

Empirical results suggest that participation in free-trade agreements has had significant effects on both trade and FDI, especially within the European Union. Quantifying these effects is particularly important for OECD countries that will join the European Union in 2004, as established in the recent Athens EU Council Meeting. Table 6 suggests that the gains from EU accession for the Czech Republic, Hungary and Poland will indeed be sizeable in terms of trade integration and FDI stocks. This is due to both increased transactions with other EU countries and (to a lesser extent) increased trade and investment flows from non-EU countries. Trade flows are estimated to increase by around 10 per cent in both directions while FDI outstocks and instocks are estimated to double relative to average levels in

Table 6. **The effects of European Union accession on trade and FDI<sup>1, 2</sup>**

	Per cent increase in exports <sup>3</sup>	Per cent increase in imports <sup>3</sup>	Per cent increase in the FDI outstock <sup>4</sup>	Per cent increase in the FDI instock <sup>4</sup>
Czech Republic	11.5 (47.2)	10.9 (49.7)	103.0 (0.4)	112.0 (24.2)
Hungary	11.2 (45.0)	10.4 (47.8)	28.1 (1.6)	107.0 (19.3)
Poland	11.6 (15.0)	10.7 (26.0)	92.2 (0.3)	104.9 (9.3)

1. The simulations are based on coefficients estimated in panel regressions of bilateral outward FDI positions on non-policy factors (distance, transport costs, market size, similarity in size and factor endowments, and other country and time-specific effects) and policy influences (FDI restrictions, tariff and non-tariff barriers, participation in free trade areas, and product and labour market arrangements). The regressions cover bilateral FDI relationships between 28 OECD countries over the 1980-2000 period.

2. Initial levels relative to GDP are in parentheses.

3. Relative to 1998 values.

4. Relative to the average level over the 1990s.

the 1990s in most countries. However, these simulation results are likely to over-estimate the actual post-accession gains to the extent that trade and FDI stocks have already been affected by the expectation of EU membership.

## SUMMARY AND CONCLUSIONS

The results of the empirical analysis suggest that border openness to trade and investment and competition-oriented domestic policies have important implications for OECD trade and FDI patterns. The main conclusions in each of the broad policy areas examined in the paper are reviewed below under four headings.

### Openness: formal trade and FDI restrictions:

- The empirical results suggest that eliminating remaining tariff and non-tariff barriers could increase significantly exports of goods within the OECD. The removal of border barriers in existing free-trade areas, such as the European Union (EU) Single Market or the North American Free-Trade Agreement (NAFTA), is estimated to have boosted both goods trade and overall FDI flows among participating countries. Likewise, simulations suggest that prospective EU membership may be associated with increasing trade flows and booming inward FDI positions for new EU members. By contrast, free-

trade areas do not seem to have increased significantly cross-border supply of services.

- A number of countries (especially outside the European Union) still have a relatively restrictive FDI environment in some important non-manufacturing industries, such as electricity, transport and telecoms. Aligning FDI restrictions on those of the most liberal country would increase significantly the OECD-wide inward FDI position.
- There is some limited evidence that stable exchange-rate arrangements may positively affect the inward FDI position of participating countries. Through this channel, countries that are members of currency unions (such as the European Monetary Union) experience further integration of their markets in both the union itself and globally. The complexity of the relationship between FDI and exchange-rate variability suggests, however, that this aggregate result may mask a variety of different responses of MNEs to the establishment of currency unions.

#### **Product-market reforms:**

- The countries with relatively restrictive and costly product-market regulations will tend to have lower stocks of foreign capital. Thus, product-market reforms that reduce the relative restrictiveness of regulations are likely to increase the level of inward FDI in a given country. OECD-wide product-market reform can raise the *overall* stocks of inward and outward FDI outstanding, thereby increasing global integration.
- Exports are negatively affected by both home and destination country anti-competitive regulations. Such home regulations may reduce both productive efficiency and the range and quality of goods supplied in foreign markets (*e.g.* through their negative effects on entry and innovation), thus regulatory reform in the home country is likely to positively affect exports. Restrictive regulations in the destination (importer) country also curb exports from the home country by making access to markets more difficult for foreign suppliers. All else equal, a general convergence of regulation in the OECD area towards the regulatory environment of the most liberal country would tend to increase within-OECD exports markedly.
- In services trade, the combined negative influence of restrictive regulations in the exporting and the importing countries is even stronger, because it affects for instance the ability of the exporting country to sell air transport, tourism or banking services to a trading partner. Unilateral or concerted efforts by OECD trading partners to implement significant competition and efficiency-enhancing reforms at both ends of the transactions are likely to boost the global volume of trade in services.

**Labour-market reforms:**

- Estimates suggest that strict employment protection legislation (EPL) and high tax wedges on labour income may sometimes affect the labour market in the home country in ways that curb its exports, for instance by making the reallocation of labour across firms, industries and occupations difficult. Similarly, by raising the cost of investment in the host country, they tend to lower its inward FDI. There are, however, important interactions between EPL and the institutional set up in the labour market as was pointed out by Calmfors and Driffill (1988) and Elmeskov *et al* (1998). When collective bargaining and other labour-market arrangements favour wage adjustments that fully offset the costs of EPL, the potentially negative effect on exports can be neutralised. In other regimes where such compensation is difficult, strict EPL is associated with significantly lower exports. By contrast, the collective bargaining regime can hardly moderate the negative influence of strict EPL on FDI. If EPL increases the risk/return ratio on foreign investment, foreign investors are likely to choose locations where this ratio is lowest, irrespective of the potentially offsetting effect of the collective bargaining regime. Empirical estimates suggest that labour-market reforms easing employment protection legislation and lowering tax wedges on labour income would boost global economic integration.

**Infrastructure:**

- Improving network infrastructure has ambiguous *a priori* effects on FDI, because inadequate infrastructure may motivate foreign investment in these industries. However, good infrastructure conditions are likely to be important for reducing transport and communication costs and increasing trade, especially in some services where international transactions require such conditions to be good in both origin and destination countries (*e.g.* freight, tourism, finance). Thus, policies that improve infrastructure can significantly increase both the bilateral and global volumes of service trade.

## NOTES

1. The other important channel of globalisation is movement of people. For a discussion of migration trends, determinants and policies see OECD (2002a). Temporary movement of personnel is also an important mode of service supply that is not covered in this study.
2. The willingness of businesses to expand cross-border activity and their localisation decisions are likely to depend to some extent also on the taxation of profits of foreign subsidiaries. Patterns of FDI taxation and their effects on global integration are studied in two companion papers (Yoo, 2003; and Hajkova *et al.*, 2003).
3. This is in line with recent economic research (OECD, 2002a; Markusen and Maskus, 2001a, 2001b) that stresses the joint determination of trade and FDI flows. However, it is important to note at the outset that, due to the level of aggregation at which the analysis is performed, the long-standing issue concerning the substitutability or complementarity of trade and FDI is only dealt with tangentially in this document. This issue has been recently (and repeatedly) addressed elsewhere in the OECD by means of literature surveys (OECD 1995, 2002b) and empirical analyses using sectoral (OECD 1996, 1997a) and aggregate data (OECD 1998a).
4. Outward and inward positions are multilateral measures of FDI activity that cumulate for each investor country the bilateral stocks held in all FDI partner (host) countries (henceforth, outstocks) and for each host country the bilateral stocks held by all partner (investor) countries (henceforth, instocks).
5. FDI activity can in principle be decomposed into *i*) mergers and acquisitions, *ii*) greenfield investments, *iii*) reinvested earnings, and *iv*) capital transfers between related enterprises. In practice, available data rarely allow such decomposition to be made.
6. For instance OECD (2002c) considers the drop as a “correction” of the investment and stock market bubble that occurred at the turn of the century. High levels of FDI flows were also partly related to a flurry of unprecedented privatisation activity.
7. Geographical specialisation indicators for FDI inflows and outflows are broadly characterised by the same patterns. However, inflows indicators suggest that a “catch up” phenomenon is taking place in some countries, such as Greece *vis-à-vis* the European Union and Korea *vis-à-vis* Japan; and outflow indicators show that several countries (including a few EU members, Canada, the United States, New Zealand and Korea) had developed a specialisation in investing in Japan over the 1995-1998 period.
8. Data for the 1980-1990 period is incomplete or missing for transition countries and Korea.
9. For instance, services provided by a barber are hardly tradable between cities or regions within a country, not to mention across borders. However, the provision of

many other services, including some of the most dynamic ones over the past two decades (such as communication, financial intermediation and business services) involves lower transportation costs, which are further decreasing as information and communication technologies (ICT) spread out. Moreover, ICT are also decreasing transportation costs for services that were traditionally not tradable, such as retail distribution (see, for instance, OECD 2001b).

10. The effects of FDI taxation are studied in Hajkova *et al* (2003).
11. Policies can also affect trade and FDI indirectly, through their effect on factor proportions, for example by improving the quality of a country's infrastructure capital or the skills of its labour force.
12. Non-tariff barriers include so-called "core" measures, such as price controls (voluntary export restraints, variable charges, anti-dumping and countervailing actions) and quantitative restrictions (non-automatic licensing, export restraints, quotas and prohibitions). See OECD (1997b) for details.
13. *Multilateral tariff and non-tariff barriers* are derived from detailed data on *ad valorem* MFN tariff rates and the frequency of non-tariff barriers in 6-digit industries of the Harmonised System of Classification (UNCTAD, 1998). The data are aggregated using average 1998 OECD import weights up to the 2-digit ISIC Rev. 3 level and average 1998 OECD value-added weights thereafter. Information about cross-country differentials in import shares for different goods (net of intra-EU imports) was exploited to differentiate trade barriers across EU countries. *Bilateral tariffs* are based on the new MacMaps data produced jointly by the Centre d'Etudes Prospectives et d'Informations Internationales and the International Trade Center (Bouet *et al.*, 2001, 2002). The MacMaps data report information on MFN duties, other *ad valorem* duties, specific duties, preferential margins, prohibitions, tariff quotas and anti-dumping (specific or *ad valorem*) duties. These are aggregated to the 2-digit ISIC Rev. 3 level using average import weights differentiated by group of trading partners. Despite the use of *average* import weights in aggregation, both the multilateral and the bilateral indicators may tend to underestimate the extent of trade barriers if import shares are depressed in industries with high barriers.
14. Moreover, by enlarging the size of the market accessed at equal trade cost by third-party countries, they could also tend to increase bilateral trade between the free-trade area and non-signatory countries, all the more so if non-signatory countries are themselves members of a different free-trade area (because the reverse phenomenon may apply). In particular, intra-industry trade may increase due to enhanced economies of scale.
15. See Markusen (2002) for an extensive discussion of the conflicting forces acting on bilateral FDI flows as trade liberalisation is implemented.
16. This could partly explain the wave of within EU mergers and acquisitions that followed the Single Market Programme.
17. Neary (2002) argues that this tendency takes the form of consolidation of different plants into a single location within the free-trade area. He also notes that the increased competition from MNEs of signatory countries can have an opposite influence on third-party investors, leading them to *reduce* investment in the free-trade area.
18. Non-statutory barriers to FDI are very difficult to ascertain and quantify. However, some of them were included in the indicators, such as the absolute barrier repre-

- sented by full state ownership of business enterprises and hidden institutional or behavioural barriers documented in official reports.
19. To a large extent, the generalised decline in restrictions reflects full liberalisation of capital flows within the European Union (completed in the early 1990s) and the concomitant extensive privatisations both in the European Union and elsewhere (*e.g.* Mexico), which have opened up previously sheltered public firms and monopolies to foreign capital.
  20. The indicators are unable to capture differences in the enforcement of restrictions, which might be particularly important for screening requirements. Also, several countries have further eased restrictions since the data were last collected.
  21. A simple count of restrictions affecting different industries shows that 67 per cent of all restrictions concern the services sector (Sauvé and Steinfatt, 2003).
  22. The simple bivariate correlation across countries between the sectoral indicators of FDI restrictions and the sectoral shares of employment in foreign affiliates is negative and significant.
  23. Clearly the more these activities are centred in the host country, the less sensitive FDI is to changes in exchange-rate volatility. In Goldberg (1993) the effect of reduced volatility on FDI is ambiguous. On the other hand, Darby *et al.* (1999) stress the possibility of a negative impact.
  24. Details on the regulatory indicators shown in the figures can be found in Nicoletti *et al.* (1999), Nicoletti *et al.* (2001) and Nicoletti and Scarpetta (2003).
  25. While regulations that bar entry or raise costs may deter FDI, regulations that are aimed at protecting intellectual property rights (IPR) may increase the attractiveness of the host country for international investors, because protection of IPR makes it more difficult to imitate their firm-specific knowledge assets (*e.g.* through the movement of managers or employees from the foreign affiliate to local firms). See Smith (2001).
  26. This idea and related empirical evidence are explored in detail in Mirza and Nicoletti (2003).
  27. The summary indicator is the GDP-weighted average of the indicators of regulation in 12 non-manufacturing industries.
  28. For instance, there is evidence that certain product market regulations can hinder firm growth and curb R&D spending (Nicoletti *et al.*, 2001; Bassanini and Ernst, 2002). Both factors can constitute a handicap for internationalisation.
  29. Other important factors include, for instance, coverage of collective agreements, minimum wages and health and safety regulations, for which cross-country data are patchy or lacking.
  30. EPL and the social expenditures that are financed through labour income taxation may also lower transaction costs in the relationship between workers and firms, reduce labour market frictions and smooth out the social costs associated with adverse labour market outcomes. Through these channels, EPL and labour income taxation can actually have positive repercussions for export prices and expected investment returns. However, these effects are difficult to measure and, in this study, the focus is on the role they play in pushing up production costs.
  31. Moreover, in the same way as product market regulations, stringent EPL and high wedges in the home country may also encourage firms to localise production in countries where labour market rules and taxation are more favourable to business, thereby

- stimulating outward FDI; but at the same time EPL may handicap firms that want to do so by hindering their potential for reorganising production or growing in size. Nicoletti *et al.* (2001) find that the average size of firms is negatively related to the stringency of EPL in a panel of OECD countries and industries.
32. This idea was first put forth by Calmfors and Driffill (1988). See Elmeskov *et al.* (1998) for evidence on the interaction between EPL and bargaining mechanisms and Daveri and Tabellini (2000) for the interaction between labour income taxation and bargaining mechanisms.
  33. It is also possible that foreign investors may find the implications of restrictive EPL provisions more difficult to ascertain than domestic investors (due to an asymmetry of information) and hence have to face higher costs.
  34. More importantly, government policies (*e.g.* access regulations) are crucial for ensuring a regulatory and business environment which is conducive to efficient private investment in infrastructure. See Gönenç *et al.* (2000) and OECD (2001b) for a detailed discussion of these issues.
  35. Yeaple and Golub (2002) attempt to test these hypotheses and provide some support for the effects of infrastructure on comparative and absolute advantage.
  36. Deardorff (1995) shows that this relationship emerges from virtually all models of trade.
  37. The role of factor proportions in explaining trade flows is clearest in Heckscher-Ohlin models of trade. Moreover, in a general gravity framework relative endowments of human and physical capital also provide information on the supply of differentiated goods, which are usually skill and capital intensive (Evenett and Keller, 2002). Their role in determining vertical FDI is emphasised in Helpman (1984) and Helpman and Krugman (1985).
  38. Markusen (2002) notes that FDI has only a *relative* advantage over trade with distant countries. Therefore, distance and transport costs may well have a negative influence on the intensity of outward FDI.
  39. As mentioned above, the “financial” FDI data used in the analysis suffer from several drawbacks (*e.g.* they do not distinguish between mergers and acquisitions and green-field investment, and may be geographically biased to the extent that MNEs use strategically-located holding companies to intermediate their investments), but the period and country coverage of the data on foreign affiliates was too limited for the purposes of empirical analysis. As regards services trade, the countries excluded are Belgium, Luxembourg, the Czech Republic, Iceland, Poland, Turkey, New Zealand, Mexico, Switzerland. Belgium and Luxembourg are excluded from partners. The Slovak Republic was also excluded from the analysis because data for other variables are missing.
  40. For similar specifications see, for instance, Markusen and Maskus (1999) and Egger (2001). The reduced form approach implies that the estimated coefficients incorporate both direct and indirect effects of the explanatory variables. For example, the parameter of tariffs in the trade equations reflects both the direct effect on trade and the indirect effect operating through the effect of tariffs on FDI and the possible impact of the induced effect of FDI on trade.
  41. The focus on FDI outstocks or instocks (instead of outflows or inflows) is justified by the fact that the decision of firms concerns the level of local production, which is a function of the desired level of the local stock of FDI.

42. The year-on-year difference of transportation costs was smoothed out to eliminate excessive volatility in the data.
43. In FDI equations, bilateral and effective exchange rates capture valuation and asset effects. In trade equations, nominal exchange rates together with the determinants of relative prices (*i.e.* relative factor endowments and policies that affect production costs) capture real competitiveness effects.
44. In addition a specific dummy for English-speaking countries was introduced to test for the possible influence of “language” effects, but no such effect was detected perhaps due to the presence of the bilateral fixed effect.
45. This transformation involves expressing the data as deviations from the values for the average home country or the average partner, which eliminates partner-specific or home country-specific effects, respectively.
46. Thus, in preliminary regressions, FDI instocks were related to both the average restrictiveness of policies in the host-country’s FTA and their restrictiveness in the host country relative to other countries within the same FTA.
47. Due to data limitations, the total instock regressions covered only 10 to 19 OECD countries, depending on the policy variables included.
48. Distance could not be estimated in bilateral FDI equations because of its purely cross-section nature. Its effect is captured by the bilateral fixed effects which are accounted for non-parametrically. Transport costs were omitted from the bilateral service trade equations for two reasons. First, the measure used in this study is constructed as the difference in CIF-FOB in manufacturing trade, which may have little relevance for trade in services. Second, transport is one component of service trade, hence transport costs are likely to be endogenous to it.
49. Related to this, persistence could be also driven by the large share of reinvested earnings in FDI flows.
50. In the total instock regressions the relevant variable is the nominal effective exchange rate, which is a trade-weighted average of bilateral exchange rates. A depreciation of this rate does not necessarily imply a depreciation of all bilateral rates. Thus, the overall effect depends on the interaction of depreciation with the country mix of bilateral trade flows.
51. The estimated effect of restrictions is similar for FDI flows, with the reduction in flows implied by the restrictions varying between 9 and 70 per cent. The estimation results for FDI outflows are reported in Nicoletti *et al* (2003).
52. Available non-tariff measures are partner-specific variables that express MFN import protection against the average OECD exporter. Thus, they do not account for bilateral arrangements and other special regimes, including non-MFN treatment and anti-dumping measures. Bilateral tariffs do account for some of these factors, but are available only for the year 2001. It should be noticed, however, that results for bilateral tariffs are robust to the adjustment of standard errors for repeated observations over the time dimension.
53. The finding that FDI is boosted by EU membership is consistent with related evidence by Pain (1997) and Pain and Lansbury (1997). Positive effects of EU membership on FDI from third-party countries were also found by Dunning (1997) and Barrell and Pain (1998).

54. In the total instock equation regulation can be interpreted as being expressed relative to the OECD average.
55. Results for IPR are not robust to the adjustment of standard errors for repeated observations over the time dimension. The relationship between IPR protection and FDI is discussed in OECD (2002g).
56. In this case, however, statistical tests rejected the hypothesis that the effect is identical in both countries. Therefore, separate coefficients were estimated for wedges in the home country and the partner.
57. Transport would seem to be the main relevant infrastructure for trade in goods. It also plays an important role in trade in services, both directly through the freight and travel components of this trade and indirectly through the tourism component.
58. Excluding the low infrastructure countries yields insignificant (though correctly signed) estimates, probably due to the lack of sufficient cross-country variability in the data.
59. The restriction that the coefficients of (the log of) infrastructure in the country and partner are the same is supported by statistical tests.
60. In particular, this kind of simulations assumes that policy moves do not change the estimated average relationships (*i.e.* the estimated regression coefficients) between trade, FDI and policies and are thus subject to the Lucas critique (Lucas, 1976). Moreover, it is assumed that these average cross-country relationships are representative of relationships in each country.
61. Since differences in the level of trade and FDI across countries are captured by dummy variables, it is not surprising that policy variables appear to play a relatively small role in contributing to the overall variance in the data.
62. The unexplained residual is generally very small in the FDI equations.
63. In the simulations, the initial stock is defined as the inward FDI position in 1998.
64. Here regulation is specific to non-manufacturing and the most liberal country in 1998 is again estimated to be the United Kingdom.

NBER Working Paper No. 9756

June 2003

JEL No. J1, J6

**ABSTRACT**

We investigate the regulation of labor markets through employment laws, collective bargaining laws, and social security laws in 85 countries. We find that richer countries regulate labor less than poorer countries do, although they have more generous social security systems. The political power of the left is associated with more stringent labor regulations and more generous social security systems. Socialist and French legal origin countries have sharply higher levels of labor regulation than do common law countries, and the inclusion of legal origin wipes out the effect of the political power of the left. Heavier regulation of labor is associated with a larger unofficial economy, lower labor force participation, and higher unemployment, especially of the young. These results are difficult to reconcile with efficiency and political power theories of institutional choice, but are broadly consistent with legal theories, according to which countries have pervasive regulatory styles inherited from the transplantation of legal systems.

## I. Introduction

Every country in the world has established a complex system of laws and institutions intended to protect the interests of workers and to guarantee a minimum standard of living to its population. In most countries, this system encompasses three bodies of law: employment law, industrial and collective relations law, and social security law. Employment laws govern the individual employment contract. Industrial and collective relations laws regulate the bargaining, adoption, and enforcement of collective agreements, the organization of trade unions, and the industrial action by workers and employers. Social security laws govern the social response to needs and conditions that have a significant impact on the quality of life, such as old age, disability, death, unemployment, and maternity.

In this paper, we examine these laws in 85 countries through the lens of three major theories of institutional choice: the efficiency theory, the political power theory, and the legal theory. The *efficiency* theory holds that institutions adjust to serve the needs of a given society most efficiently. Each society chooses a system of social control of business that optimally combines market forces, dispute resolution in court, government regulation, and corrective taxes and subsidies. Under the *political power* theory, institutions are shaped by those in power to benefit themselves at the expense of those out of power. Both voting and interest group politics allow the winners to benefit at the expense of the losers, with checks and balances on the government limiting the extent of redistribution. Finally, under the *legal* theory, a country's approach to regulation is shaped by its legal tradition. Common and civil law countries utilize different strategies for dealing with market failure: the former relying on contract and private litigation, the latter on direct supervision of markets by the government. Under this theory, the

historical origin of a country's laws shapes its regulation of labor and other markets.<sup>2</sup>

Our focus on labor laws might be particularly helpful in distinguishing the political power theory from the legal theory. Roe (2000) and Pagano and Volpin (2000) have recently argued that the political power of labor has been central to legal and regulatory design of the 20<sup>th</sup> century (Roe 2000, Pagano and Volpin 2000). Using data on OECD countries, these authors challenge the observation of La Porta et al. (1997, 1998) that the differences in financial development among common and civil law countries are best understood in terms of legal theories. Roe (2000) in particular argues that civil law is simply a proxy for social democracy. An analysis of labor laws gives these political theories their best shot, for two reasons. First, we expect leftist governments to focus on labor regulations as a top priority for benefitting their supporters. Second, because labor laws are relatively recent, we would not necessarily expect a profound influence of the commercial legal tradition on their structure.

To assess these theories, we collect data on employment laws, collective bargaining laws, and social security laws as of 1997 for the Djankov et al. (2002) sample of 85 countries, and code these data to come up with a variety of measures of worker protection. We combine these data with already existing (and some newly collected) information on economic development, leftist orientation of governments, union power, political and economic constraints on government action, and legal origins to examine the determinants of the regulation of labor. We also examine data on the unofficial economy, labor force participation, unemployment, and relative wages to consider who benefits and who loses from the regulation of labor.

The available research on labor regulations is more extensive than that on most other

---

<sup>2</sup>In footnotes, we also consider the cultural theory, under which regulations are shaped by a country's cultural history, such as the dominance of particular religious groups. The data do not support this theory, so we keep its discussion to a minimum.

laws. The Organization of Economic Cooperation and Development has sponsored the creation of a database of labor regulations in member countries (Nicoletti, Scarpetta, and Boylaud 1999; Nicoletti and Pryor 2001). The World Bank has assembled a data base of International Labor Office certifications for 119 countries, which provide a partial view of the labor laws as well (Forteza and Rama 2000). Heckman and Pages-Serra (2000) collect and examine an extensive data set of job security regulation for Latin American and Caribbean countries. Mulligan and Sala-i-Martin (2000) assemble and analyze data on social security systems. What distinguishes our data from the previous efforts is a combination of a significant coverage of countries and a comprehensive approach to labor market regulations.<sup>3</sup>

In the next section, we briefly describe some of the principal theories of the determinants of labor regulations and develop our hypotheses. In section III, we describe the data. In section IV, we present the data on the regulation of labor, and describe some of its basic regularities. In sections V and VI, we present the tests of alternative theories. Section VII concludes.

## **II. Hypotheses**

### *Efficiency*

Demsetz (1967) and North (1981) propose that the choice of institutions is dictated primarily by efficiency considerations. In their original form, these theories hold that there are fixed costs of setting up institutions, and that it becomes socially efficient to set them up only when the benefits cover the costs. More recently, research on efficient institutional choice has focused on the idea that different institutional arrangements, ranging from reliance on unbridled

---

<sup>3</sup>There is also an extensive literature on the consequences of regulation of labor, including Lazear (1990), Besley and Burgess (2002), Fonseca, Lopez-Garcia, and Pissarides (2000), Heckman and Pages-Serra (2000), and Ichniowski, Freeman, and Lauer (1989), among others.

market forces, to contract and private litigation, to government regulation, to subsidies and social insurance, represent alternative modes of dealing with torts and market failures, which may be appropriate in different circumstances.<sup>4</sup> For example, different combinations of these strategies may be efficient in developed and developing countries.

Here we consider two versions of this theory. The first focuses on the distinction between regulation and social insurance. Social insurance may be the relatively more efficient way of dealing with market failures in countries with a lower social marginal cost of tax revenues, which presumably are the richer countries (Brennan and Buchanan 1980, Becker and Mulligan 2000). Poor countries must then regulate to protect workers from being fired or mistreated by employers, whereas rich countries provide unemployment insurance, sick leave, early retirement and so on because they can more cheaply raise taxes to finance such operations (Blanchard 2002). A similar argument would maintain that rich countries can better rely on courts and contracts to address potential market failures, including those in the labor market, and so do not need as much regulation as do poor countries, where contracts cannot be enforced.

The second version of the efficiency argument predicts exactly the opposite. It holds that the principal cost of regulation, relative to other forms of social control of business, is its potential for abuse of regulated firms by the government and its officials. Labor regulations can be used to force firms to hire and keep excess labor, to empower unions friendly with the government, etc. According to this argument, the rich and better governed countries have a comparative advantage at regulation relative to other forms of social control of business because their governments are less likely to abuse power. This view with respect to regulation in general

---

<sup>4</sup>This argument is developed in Glaeser and Shleifer (2002, 2003), Glaeser, Scheinkman and Shleifer (2003), and Djankov et al. (2003b).

is described by Djankov et al. (2003b).

The basic thrust of efficiency theories is that countries at different levels of economic development should adopt different regulatory structures. The variation in patterns of regulation can also suggest which efficiency forces, if any, shape the regulation of labor. We note, however, that labor markets are not an ideal testing ground for efficiency theories, because the basic assumption of market failure is not nearly as convincing in those markets as in some others, and because there is no compelling argument that labor laws evolved toward efficiency through a long period of testing and social negotiation.

### *Political Power*

According to political power theories, institutions are designed not to pursue efficiency, but to transfer resources from those out of political power to those in power, as well as to entrench those in political power at the helm (Marx 1872, Olson 1993, Finer 1997). According to this view, institutions are not only generally inefficient, but are in fact designed to be so by political leaders to help themselves and their favored groups.

Political power theories come in two basic varieties. The first holds that the principal mode of political decision making is elections, and therefore the parties that win elections get to shape laws. The second variety, which applies to both democracies and dictatorships, holds that laws are shaped by the influence of interest groups (Olson 1965, Becker 1983).

Political power theories are by far the dominant explanation of the choice of labor regulations. In the electoral version, they hold that regulations protecting workers (or at least employed workers) are introduced by socialist, social-democratic, and more generally leftist governments to benefit their political constituencies (Esping-Andersen 1999, Hicks 1999). In

the interest group version, these theories hold that labor regulations are a response to the pressure from trade unions, and therefore should be more extensive when the unions are more powerful, regardless of which government is in charge.

Political theories also hold that the ability of those in power to use regulations to benefit themselves is limited by checks and balances on the government, which can come either from politics (Buchanan and Tullock 1962) or from markets. Dictatorships are less constrained than democratically elected governments, and therefore will have more redistributive laws and institutions. Constitutions, legislative constraints, and other forms of checks and balances are all conducive to fewer regulations. This theory found some empirical support in our previous work on the regulation of entry (Djankov et al. 2002). Likewise, economies open to trade may be less likely to introduce expensive regulations, because competition makes it less lucrative for governments to raise firms' regulatory costs (Ades and DiTella 1999, Rajan and Zingales 2003).

### *Legal Theory*

Legal theory has received considerable attention in the discussions of institutional evolution in the last several years. Two very distinct legal traditions evolved in Western Europe since the 12<sup>th</sup> century: common law and civil law. Common law emerged in England and is characterized most clearly by the importance of decision making by juries, independent judges, and the emphasis on judicial discretion as opposed to codes. From England, common law was transplanted to its colonies, including Ireland, U.S., Canada, Australia, New Zealand, India, Pakistan and other countries in South and East Asia, East Africa and the Caribbean.

Civil law evolved from Roman law in Western Europe through the middle ages, and was incorporated into civil codes in France and Germany in the 19<sup>th</sup> century. Civil law is

characterized by less independent judiciaries, the relative unimportance of juries, and a greater role of both substantive and procedural codes as opposed to judicial discretion. Through Napoleonic conquest French civil law was transplanted throughout Western Europe, including Spain, Portugal, Italy, Belgium, and Holland, and subsequently to the colonies in North and West Africa, all of Latin America, and parts of Asia.

The German code became accepted in Germanic Western Europe, but also was transplanted to Japan and from there to China, Korea, and Taiwan. Socialist law was adopted in countries that came under the influence of U.S.S.R., while an indigenous Scandinavian legal tradition developed in Sweden, Norway, Denmark, Iceland and Finland.

The legal theory holds that countries in different legal traditions utilize different institutional technologies for social control of business (Djankov et al. 2003b). Common law countries tend to rely more on markets and contracts, and civil law (and socialist) countries on regulation (and state ownership).<sup>5</sup> For the labor market, this implies that civil law countries and socialist law countries should regulate labor markets more extensively than common law countries. The legal theory would also predict that common law countries should have a less generous social security system, because they are more likely to rely on markets to provide insurance. Perhaps most importantly, the legal theory predicts that patterns of regulation of different activities are correlated across countries. These predictions are tested below.<sup>6</sup>

---

<sup>5</sup>Legal theories have been tested in other areas of law. Compared to civil law and particularly French civil law countries, common law countries have better legal protection of shareholders and creditors (La Porta et al. 1997, 1998), lighter regulation of entry (Djankov et al. 2002), less formalized legal procedures for resolving disputes (Djankov et al. 2003a), and securities laws more focused on private contracting than regulation (La Porta et al. 2003a).

<sup>6</sup>Because legal systems were transplanted largely through conquest and colonization, one can argue that the influence of the legal origin is an exogenous determinant of institutional choice.

Legal theories have been challenged by advocates of political power theories, such as Roe (2000) and Pagano and Volpin (2000), who argue that at least in Western Europe, the civil law tradition has often coincided with the political pressure to regulate, usually coming from the left. By combining extensive data on political orientation and legal origins for a sample of 85 countries, we attempt to distinguish the pure political power from the pure legal theory. We also argue, at the end of the paper, that reality is probably best described by a hybrid model.

### **III. Measures of Labor Regulation**

We construct a new data set describing the legal protection of workers in 85 countries in 1997. We gather data on the three components of the legal framework for worker protection: (i) employment laws; (ii) industrial (collective) relations laws, and (iii) social security laws.

To identify issues subject to statutory regulation in the area of employment and industrial relations laws, we use the OECD Jobs Study (1994) and the International Encyclopaedia for Labor Law and Industrial Relations. For social security laws, we follow the de-commodification index of Esping-Andersen (1999), regarded as a leading empirical comparison of social security systems among developed countries (Hicks, 1999, p. 249). We also rely on several cross-country secondary sources, including the International Encyclopaedia for Labour Law and Industrial Relations, the ILO's Conditions of Work Digest (1994, 1995), and the U.S. Social Security Administration's Social Security Programs Throughout the World. For each law in each country, we identify the government regulation of each specific area, and assign a higher score when a regulation is more protective of a worker. We then construct indices for each area of the law that aggregate these scores. Table I contains detailed definitions of all the variables used in the paper.

To ensure comparability and consistency across countries, we consider a “standardized” male worker with the following characteristics: (i) he is a non-executive full-time employee working in the same firm for 20 years;<sup>7</sup> (ii) his salary plus benefits equals the country's GNP per worker during the entire period of employment; (iii) he has a non-working wife and two children, and the family has always resided in the country's most populous city; (iv) he is a lawful citizen who belongs to the same race and religion as the majority of the country's population; and (v) he is not a member of a labor union (unless membership is mandatory). For social security, we also assume that the worker retires at the normal retirement age as defined by the country's laws; sickness lasts for 2 months; and the unemployment spell lasts for one year. We also assume a “standardized” employer with the following characteristics: (i) it is a manufacturing company wholly owned by nationals; (ii) its legal domicile and main place of business is the country's most populous city; (iii) it has 201 workers; and (iv) it abides by every law and regulation, but does not grant workers more prerogatives than are legally mandated. Also, (i) when both a standard duration and a possible extended period of time are provided by law, we choose the standard period; (ii) we use 30-day months and assume 22 working days per month and 5 working days per week; and (iii) when we find complementary coverage mechanisms, all applicable mechanisms are taken into account.

### *Employment laws*

Employment laws govern the individual employment relation, including the formation of the individual labor contract, the mandatory minimum terms and conditions of such contract, and

---

<sup>7</sup>Results are similar for a worker with only three years of employment.

the termination of the contractual relation. Accordingly, we group the provisions of employment laws into three broad areas: (i) alternative employment contracts; (ii) conditions of employment; and (iii) job security. For each area, we collect several indicators and aggregate them into sub-indices and then the overall index of employment laws. We follow the same procedure for industrial relations and social security laws.

The first broad area covers restrictions placed on alternative employment contracts. If the regulation of alternative contracts is more flexible than that of regular contracts, the former will be used to by-pass standard labor provisions. The three main alternatives to the standard employment contract are part-time, fixed-term, and family members' contracts. Workers hired under such contracts are typically paid lower benefits and are subject to less onerous termination rules. Our indicators in the alternative employment contracts sub-index cover both the permissibility and the characteristics of these contracts.

The second broad area covers the conditions of the employment contract. The legal provisions here cover three areas: (i) flexibility on working time requirements (including mandatory daily rest, maximum number of hours in a work week, premium for overtime, and restrictions on work at night and on weekends); (ii) mandatory payment for non-working days (including paid annual leave, holidays, and maternity leave); and (iii) minimum wage legislation.

The third broad area is job security, or legal protection against dismissal, which encompasses: (i) grounds for dismissal; (ii) procedures for dismissal; (iii) notice period; (iv) severance payment; and (v) the constitutional principles covering protection against dismissal.

The rules on grounds for dismissal range from 'contract at will,' where the employment relation may be terminated by either party at any time and with no limitations other than those contained in the agreement, to allowing the termination of employment contracts only under a

very narrow list of ‘fair’ causes that may not be contracted around by the parties, to refusing to consider dismissal on economic necessity (redundancy) as a fair cause for firing employees. The law may restrict the employer’s freedom to dismiss by requiring mandatory notification or even the approval from unions, workers councils, the public employment service, a labor inspector, or a judge. Some countries also require rehabilitative measures (retraining and allocation of another job within the enterprise) prior to the dismissal, and establish priority rules for dismissal or re-employment of redundant workers. Job security regulations also cover the timing and the cost of dismissal. Some countries mandate a lengthy advance notice for termination, while others leave this issue to the individual employment contract. Similarly, the termination of the employment agreement sometimes carries no payment at all or a payment in lieu of notice.

### *Industrial relations laws*

Industrial relations laws aim at collectively protecting workers from employers.<sup>8</sup> They govern the balance of power between labor unions and other forms of organized work, and employers and associations of employers. We aggregate industrial relations laws into three sub-indices: (i) collective bargaining; (ii) workers’ participation in the company’s management; and (iii) collective disputes (strikes and lockouts), and then aggregate those into an index.

Collective bargaining covers several areas. First, some countries require employers to bargain with organized workers (e.g., unions and workers’ councils), while others allow them to refuse to do so. Second, in some countries collective agreements are extended to third parties as

---

<sup>8</sup> Some provisions aim to protect workers from other workers. For instance, “right-to-work” laws in the U.S. protect workers from unions by prohibiting the exclusive hiring of union labor. Such cases are rare and the bulk of industrial relations provisions directly protect workers from employers.

a matter of public policy at the national or sectoral levels, whereas in others they only extend to non-signatory workers at the plant level, or only bind the parties to the agreement. Third, the laws of some countries include rules requiring the exclusive hiring of union labor in certain industries or factories (closed shops).

The second sub-index captures worker participation in management, which may take the form of mandatory appointment of workers to the board of directors (the German model of co-determination), or workers councils (the Swedish model). Most countries do not provide a mechanism for worker participation. These two variables (and the presence of worker participation in the constitution) form the sub-index of worker participation in management.

The third sub-index covers the regulation of collective disputes. This area covers: (i) legal strikes; (ii) procedural restrictions to strikes; (iii) employer defenses; (iv) compulsory arbitration; and (v) the constitutional protection of the right to strike. A few nations have a straight prohibition of strikes; others limit the types of lawful strikes. For example, solidarity strikes (to support the claims of workers other than the striking workers), wildcat strikes (not authorized by the labor union), political strikes, and sit-ins are often prohibited. Procedural restrictions on the right to strike include majority voting, advance notice requirements, prohibitions on strikes while a collective agreement is in force, and the obligation to go through conciliation procedures before the strike may take place. Restrictions on employer defenses may include bans on employers' strikes (lock-outs) and on employers' retribution against strikers, such as the termination of employment of striking workers and the hiring of replacement labor during a lawful strike. Importantly, in many countries, the employer or both of the parties may be subject to arbitration against their will. Finally, the right to industrial action may be protected by the constitution.

*Social Security laws*

The bulk of social security expenditure across countries addresses old-age pensions, sickness and healthcare coverage, and unemployment. Following the design of the de-commodification index of Esping-Anderson<sup>9</sup>, our variables cover the risks of: (i) old age, disability, and death, with an emphasis on old age; (ii) sickness and health, with an emphasis on sickness; and (iii) unemployment. We code five variables for each one of these three risks. The first is always a dummy measuring whether the laws of the country provide for a mandatory and comprehensive social security system to cover the particular risk.

For the sub-index of old age, disability and death, the other four indicators are created as follows. First, the generosity of pension protection is calculated as the normalized difference between the legal retirement age and the worker's life expectancy. The second indicator is the required time of contributions to access a pension. We measure the number of months of contribution or of covered employment required by law to qualify for a standard pension. The third indicator is the percentage of the worker's monthly salary deducted by law to cover old-age, disability, and death benefits. Our last indicator of the level of protection of the pension system is the "replacement rate," calculated as the percentage of the pre-retirement salary covered by the standard old-age cash-benefit pension.<sup>10</sup> We use a similar methodology for the sub-indices of sickness and health, and of unemployment.

---

<sup>9</sup> Esping-Anderson used the share of the relevant population covered as a weight for the variables in his index for 18 developed countries. This information is not available for a large sample of countries, so we present the un-weighted data. The correlation between the Esping-Anderson index and our index of social security laws for the 18 countries in his sample is 0.47.

<sup>10</sup>Countries vary in the type of pension system they have, including lump-sum systems, private systems, and systems that provide fixed benefits to everyone. Table I describes the details of how the calculations are made depending on the type of the pension system.

### *Independent Variables*

We assemble data on a number of potential determinants of labor regulations, as well as some labor market outcomes. We measure the level of development using the (logarithm of) per capita income in 1997 – the same year as when the regulations are measured.

To measure government orientation, we expand the World Bank data base, which records the fraction of years between 1975 and 1995 that a chief executive and the largest party in the legislature in each country was rightist, leftist, or centrist. We present results for three variables measuring leftist government (these variables yield the strongest results in favor of the political theory): (i) chief executive of left or center orientation; (ii) legislature of left or center orientation; and (iii) chief executive AND legislature of left or center orientation. We rely on union density and the percentage of the labor force covered by collective agreements as proxies for the influence of labor interest groups.

To measure political constraints, we take from Djankov et al. (2002) constraints on executive power, effectiveness of legislature, and autocracy. To measure economic constraints, we take from Frankel and Romer (1999) actual trade openness in 1985, geographic openness, and factor accumulation openness. To test legal theories, we use the legal origin of commercial laws from La Porta et al. (1999). Labor market outcomes include the size of the unofficial economy, labor force participation, unemployment including that of the young, and a crude measure of relative wages of protected and unprotected workers.

## **IV. A Look at the Data**

Table II presents the sub-indices and indices of employment protection and industrial relation laws for each country in the sample. Countries are ordered by per capita income in 1997 and divided into the poorest quartile, the next 50 percent, and the richest quartile. We also compare the means and the medians of the various sub-indices and indices across income groups. Recall that all variables are coded so higher values mean more protection/regulation.

A comparison of New Zealand and Portugal, two countries of roughly similar incomes close to the top of the middle group, illustrates our indices. In the area of employment laws, fixed term contracts can be entered in New Zealand for any reason, and there is no maximum duration period provided by law. In Portugal, such contracts are allowed only for specific situations (such as substitution for another worker or seasonal activity) and are temporary in nature. The Portuguese Constitution regulates working times and leaves, remuneration, and working conditions, matters that in New Zealand are normally regulated by collective bargaining and individual employment contracts. Premium for overtime work in Portugal ranges from 50% to 75%, there are restrictions on night work, and there are 24 days of paid annual leave. New Zealand mandates no premium for overtime work, there are no restrictions on night work, and paid annual leave is 15 days. New Zealand allows “contracts at will,” which can be terminated with notice by either party without cause. Portugal has a public policy list of fair grounds for termination and stringent procedural limitations on dismissal, such as mandatory notification of the government and priority rules for re-employment of redundant workers. In New Zealand, “reasonable notice” is required to dismiss a worker, in Portugal the length of such notice is mandated by law. The employment laws index in Portugal is 2.36 (one of the highest in the world); in New Zealand it is 1.06 (one of the lowest in the world).

In the area of industrial relations laws, the Portuguese Constitution includes the rights to engage in collective bargaining and collective disputes, the right to form trade unions, and the rights of such unions to participate in the management of individual companies and in greater political issues and bodies. Employer defenses against strikes are prohibited by the Constitution. Employers have a legal duty to bargain with unions, collective agreements are extended to third parties by law, workers councils are mandatory, and employer lockouts are prohibited. In New Zealand, none of these issues are covered in the Constitution, and most are not even regulated by law. Employers have no legal obligation to bargain with unions, collective agreements are not legally extended, labor participation in management is not mandatory, and employer lockouts are allowed. Portugal's collective relations laws index is 2.26, compared to 0.43 for New Zealand.

Finally, although social security is regulated by the Constitution in Portugal but not in New Zealand, both countries have similar – and generous – social security systems, with each scoring 2.15. We show below that New Zealand and Portugal are representative of broader patterns in the data.

As Table II shows, most countries restrict alternative employment contracts, conditions of employment, and job security. There is little evidence of any major difference in regulation between the poorest and the middle income countries, but there is clear evidence that the richest countries, if anything, protect employment *less*.

With respect to industrial relations laws, collective bargaining mandates are extremely common, but appear to be more so in middle income countries than in either the poorest or the richest countries. Worker participation in management is uncommon everywhere. The regulation of collective disputes is similar across income groups. For the overall index of

regulation of industrial relations, collective bargaining mandates dominate, and show the greatest empowerment of collective bargaining in the middle income countries.

Table III focuses on social security protections. Here the results are clear: richer countries have more extensive social security protection in all areas, including old age, disability and death, sickness, and unemployment. Indeed, few poor nations have social security programs for sickness (54%) and unemployment (27%) as compared to the almost 100% availability of these programs in the richest countries. The three sub-indices describing the scope of social security benefits tell a similar story.

Table IV presents the correlations among our variables. First, looking across countries, the correlation between our index of employment laws and that of social security laws is 0.0746, which argues against the view that regulation and social insurance are substitutes. Second, leftism and legal origin are weakly correlated other than in socialist countries. This allows us to empirically separate the role of leftist politics and legal traditions in shaping labor laws.

## **V. Testing the Theories**

In Table V, we examine the relationship between the protection of workers and legal origin, holding income constant. We present the results for all three areas of law. The results confirm our earlier finding that employment protection is generally weaker in richer countries, regulation of industrial relations does not monotonically depend on income, and social security protections increase sharply with income. The results further show that, relative to common law countries, socialist and French legal origin countries mandate sharply higher employment protection. German legal origin countries have somewhat higher employment protection than do the common law countries (but not in the area of restricting employment contracts), while

Scandinavian countries are about the same as the common law countries. The magnitude of the difference between common law and French civil law countries (holding GNP per capita constant) is large: it is 1.25 times the difference between the richest and the poorest countries.

In the area of industrial relations, we see a somewhat different pattern. As with worker protection, socialist and French legal origin countries have sharply higher worker protection through industrial relations laws than do the common law countries. But here, although the evidence for the sub-indices is weak, German and Scandinavian law countries have more protective collective relations laws than do the common law countries.

In the area of social security, there is clear evidence of more generous regulation in the socialist legal origin countries than in the common law countries (except in the area of old age benefits). Next to the socialist countries, the Scandinavian countries have the most generous social security systems relative to the common law countries. The difference between French civil law and common law countries is less pronounced, and is the highest for sickness and health benefits. There is no statistically significant difference between German legal origin and common law countries in the generosity of social security schemes.

Table V delivers a preliminary message. In the protection of workers through employment and industrial relations laws, we see a repetition of a now well-documented result that civil law countries, and especially French civil law countries, regulate markets more heavily than do the common law countries (La Porta et al. 1999, Djankov et al. 2002). Perhaps the most striking fact about these regressions is the high  $R^2$ 's: 52% for the employment laws index, 33% for the industrial relations laws index, and 66% for of the social security laws index (where per capita income has significant explanatory power).

Table VI examines the effect of left political power on the protection of workers. First, countries with longer histories of leftist or centrist governments between 1975 and 1995 have heavier regulation of labor markets, as measured by either employment or industrial relations laws. In addition, on any measure of leftist/centrist government, countries with a longer history of such government have more generous social security laws.<sup>11</sup> Second, a higher percentage of the labor force covered by collective agreements is associated with more protective employment and industrial relations laws, though not with more generous social security systems. In contrast, union density is associated with more generous social security systems although it does not influence labor laws significantly. Third, the explanatory power of the political variables is sharply lower than that of legal origins in Table V. The bottom line of Table VI is that the measures of leftism are associated with heavier labor regulation, although their explanatory power is smaller than that of legal origin.

Table VII presents the results of a horse race between legal origins and measures of leftist government. We run these regressions without socialist countries, since law and politics are nearly perfectly correlated among those countries. Except for social security laws, where there is marginal evidence of greater generosity in more leftist countries, the effect of our political variables on labor laws disappears. On the other hand, the effects of legal origins remain highly statistically significant, and the coefficients hardly change. We conclude that the

---

<sup>11</sup>These results also hold, although at lower level of statistical significance, if we use the pure leftist government variables (rather than the combination of leftist and centrist governments). As an additional robustness check, on the theory that many labor laws were adopted before 1975, we rerun these regressions using a new data set on political coloration of governments starting in 1928. For these longer horizon variables, there is no evidence that the fraction of years that the leftist (or leftist/centrist) executives, or legislatures, or both, spent in office has influenced the structure of employment and collective relations laws. All measures of leftist power continue to be associated with more generous social security regimes, a fact that undermines the claim that we have a poor measure of leftist power.

effects of legal origin on the regulation of labor are much larger and more pronounced than those of politics.<sup>12</sup>

Several findings emerge from this section. First, socialist and French legal origin countries are more interventionist in their employment protection and industrial relations laws than are common law countries. Second, leftist government and higher union influence are associated with heavier regulation of labor markets, although these results are not consistent across specifications and do not survive the inclusion of legal origin in the regression. The evidence so far provides strong support for legal theories, is consistent with a particular version of the efficiency theory, and does not lend much support for the political theory. Moreover, the results (including the correlations) reject the view that legal origin and leftism are the same thing.

## VI. Further Tests

In this section, we examine four additional pieces of evidence bearing on alternative theories. First, we ask whether political and economic constraints on government reduce the regulation of labor, as the political theory would predict. Second, we ask whether politics matters for regulation *within* legal origin, which is a hybrid legal/political hypothesis. In addition, we present some evidence bearing on the strong prediction of the legal theory, namely that countries have regulatory styles, and that therefore there should be a strong correlation across countries of the extent of regulation of *different* activities. Finally, we examine some of

---

<sup>12</sup>We also considered the effects of the religious composition of the population in 1900 -- our proxy for culture -- on contemporary labor laws. There are a few statistically significant coefficients indicating that catholic countries have more protective labor laws, but the evidence is weak, and does not survive a horse race with legal origin.

the consequences of labor regulation with the twin goals of testing the efficiency theories and of understanding who gains and loses from the regulation of labor.

### *Constraints on Government*

Under the political theory, a more constrained executive would pursue less aggressive policies favoring his supporters at the expense of others, such as the regulation of labor. Constraints can come from politics itself: autocrats are less constrained than elected officials, effective legislatures can restrain the sovereign, constitutions may include checks and balances (Brennan and Buchanan 1980, Henisz 2000, La Porta et al. 2003b). Alternatively, constraints can come from markets, and in particular, openness to trade raises the cost of labor market intervention and thus may reduce it (Ades and DiTella 1999, Rajan and Zingales 2003).<sup>13</sup> The prediction of the political theory is that such constraints would be associated with lower levels of government regulation of labor, other things equal.

Table VIII presents the correlations between our six measures of economic and political constraints and other determinants of the regulation of labor. The three measures of political constraints are strongly correlated with each other, as well as with the level of per capita income. This fact presents a problem for testing political constraints theories, since the measures of political constraints may just reflect some other country characteristic associated with development. The three measures of trade openness are also highly correlated with each other, but only factor accumulation openness is highly correlated with income. On the other hand,

---

<sup>13</sup>Openness to trade may be endogenous, but we follow Frankel and Romer (1999) in also using a measure of “natural openness,” which is determined by a country’s geography.

except for the fact that governments in socialist countries face few economic and political constraints, the constraint variables are not strongly correlated with legal origins.

Table IX examines the effect of constraints on government on regulation. The table shows that more constrained governments have lighter regulation of labor markets in both the employment protection and industrial relations areas. The results hold as well if we exclude socialist countries. Basically, every measure of constraints except factor accumulation openness works. The constraints variables also eliminate the negative effect of development on employment regulation. Put differently, that effect might have come from the fact that richer countries have more constrained governments. Despite the statistical significance of the coefficients, the explanatory power of these constraints is sharply lower than that of legal origins. With respect to social security, the evidence is less consistent, but again shows that more constrained governments have smaller systems.

In Table X, we restrict the sample to non-socialist countries, and check whether these effects of political and economic constraints remain significant once we control for legal origin. The results for political constraints disappear, those for openness become a bit stronger. Legal origin remains a very important determinant of the patterns of labor market regulation.

### *Regulation Within Legal Origin*

It may be possible to treat the legal and the political theories as complementary. The former holds that civil law countries, particularly the French civil law countries, specialize in regulation as a means of social control of business, whereas the common law countries specialize in contracts and markets. Because of transplantation, these patterns of institutional specialization are largely exogenous. One could further argue that, because of such

specialization, French civil law countries are more likely to respond to the increased political demand for regulation by having more of it than do the common law countries, since the marginal social cost of providing such regulation is lower. Put differently, civil law provides a ready tool box for regulation, whereas common law is not nearly as user-friendly because of its emphasis on contracts. This logic predicts that there should be a stronger positive association between leftism and regulation in French civil law than in common law countries.

Table XI shows that, indeed, within French civil law but not within common law countries, leftism is associated with more protective employment and industrial relations laws. The difference in slope coefficients on our measures of leftism between common and French civil law countries is typically statistically significant. This result still puts the legal theory center stage, and surely does not support the view that legal origin is a proxy for social democracy. On the other hand, the result points to a hybrid view that within the institutional technologies dictated by legal systems, politics indeed plays a role in regulatory choice.

### *Regulation Across Activities*

One of the strongest implications of the legal hypothesis is that societies have regulatory styles shaped in part by their legal systems, and that therefore societies that regulate one activity are also expected to regulate others, which might be totally unrelated. We have already shown in earlier work that French civil law countries regulate entry of new firms, dispute resolution in courts, and other activities more heavily than do common law countries (La Porta et al. 1999, Djankov et al. 2002, 2003a). The findings of this paper are broadly consistent with this research.

Table XII presents the correlations between our new measures of regulation of labor markets and the measures of regulation of entry from Djankov et al. (2002) and measures of legal formalism from Djankov et al. (2003a). The data show that all these aspects of regulation go together, even though the methodologies of data collection differ tremendously across the three studies. The correlation between the employment law index and the judicial formalism index is 0.48 for one case, and 0.58 for the other. The correlation between the employment law index and the logarithm of the number of steps required to start a business is 0.62. These correlations fall by about 0.05 if we exclude socialist countries, but remain highly statistically significant. Regulatory style is pervasive across activities -- a striking confirmation of the legal theory.

Combined with the previous findings of the interaction between legal origin and politics, these results suggest that countries have regulatory styles, shaped primarily by transplantation of legal systems. Politics plays a role within the general regulatory framework presented by these styles, but it is neither as important as the styles themselves, nor is it a proxy for them.

### *Outcomes*

Finally, we consider some of the consequences of the regulation of labor. Theoretically, this is of interest for two reasons. First, efficiency theories predict that heavier regulation of labor markets should be associated with better, and certainly not worse, labor market outcomes. This prediction has been contradicted by a variety of empirical studies from Lazear (1990) to Besley and Burgess (2002), and here we confirm their findings. Second, if the regulation of labor is damaging at least to some workers, then who benefits from it? Put differently, is there political support for the heavier regulation of labor, or does legal origin simply provide a

politically unsupported “technology” for the social control of labor markets? Since, as we have already shown, more leftist governments in French civil law countries regulate labor markets more heavily, we expect to find some beneficiaries of such regulation.

We look at several potential consequences of labor regulation. These include the size of and the employment in the unofficial economy, male and female participation in the labor force, and unemployment computed separately for everyone, and for male and female workers aged 20-24. In addition, as a crude measure of relative wages of protected and unprotected workers, we consider the average wage of machine operators relative to that of clerks and workers in craft and related trades. All of these variables have related measurement problems, particularly for the developing countries, where some employment is informal and is not recorded in official statistics. Still, by looking at the various dimensions of the data, we hope to get a general picture.

The results in Table XIII are consistent across specifications and reveal no evidence that the regulation of labor is beneficial. An increase of the employment laws index by 1 point (from New Zealand to Spain) raises the share of the unofficial economy in GDP by 6.72 percentage points, the share of unofficial employment by 13.74 percentage points, and reduces labor force participation of men and women by about 3 percentage points. It also raises the average unemployment rate by nearly 3 percentage points, and that of young men by over 6 and young women by nearly 10 percentage points. The adverse effects of regulation are only slightly weaker for industrial relations laws, but are generally insignificant for social security laws.

In addition to the especially large effects of the regulation of labor on the unofficial economy and the unemployment of the young, Table XIII shows that heavier regulation is also associated with higher wages of machine operators relative to those of clerks. These results suggest indirectly that the older workers, employed in official sector and protected by the law,

are the likely beneficiaries of regulation. The costs of the regulation are borne disproportionately by the younger workers, and those employed in the unofficial economy. The heavier regulation of labor thus has its own political base: the older and better protected workers, a finding broadly consistent with other research in labor economics (Blanchflower and Freeman 2000).

Table XIV addresses the concern that labor laws are endogenous, and presents instrumental variables regressions using legal origins as instruments. With the exception of the results on the informal economy, which lose significance, the effect of employment laws on outcomes becomes stronger. The fact that the exogenous component of labor laws reduces labor force participation and raises unemployment is strong evidence against the efficiency theory.

The results on outcomes point to a possible role of politics in shaping the patterns of labor regulation. It remains the case that the most pervasive determinant of these patterns is the origin of a country's laws. But employment protection and industrial relations laws also appear to affect different classes of workers differently, and as such may create a basis of political support for the politicians who expand them. Our finding that leftist parties in French civil law countries introduce more protective labor laws is consistent with this interpretation.

## **VII. Conclusion**

There are three broad theories of government regulation of labor. Efficiency theories hold that regulations adjust to most efficiently address the problems of market failure. Political theories hold that regulations are used by the political leaders to benefit themselves and their allies. Legal theories hold that the patterns of regulation are shaped by each country's legal

tradition, which is to a significant extent determined by transplantation of a few legal systems. We examined the regulation of labor markets in 85 countries through the lens of these theories.

The evidence is inconsistent with the efficiency theory since, contrary to its predictions, poor countries regulate labor markets more than rich countries do, social security is not a substitute for labor regulation, and such regulation has adverse consequences for unemployment, labor force participation, and economic activity staying official. The evidence is also inconsistent with a basic version of the political theory, which sees heavier regulation of labor as a reflection of the political power of the left through either elected office or labor unions. Although our measures of the power of the left, as well as our measures of political and economic constraints on government, influence the patterns of regulation of labor, these effects disappear once we control for the basic regulatory style determined by the legal tradition. Finally, the evidence is broadly consistent with the legal theory, according to which patterns of regulation across countries are shaped largely by their legal structure, which arrived to most countries through transplantation of legal systems.

These results do not mean that efficiency forces in regulation are unimportant, and indeed our focus on labor markets and on a large sample of developing countries, which inherited their regulatory styles, predisposes our findings against supporting the efficiency hypothesis. These findings also do not mean that politics is unimportant, except to the extent that they reject the view that civil law is nothing but a reflection of “social democracy”. Indeed, we show that politics do influence the intensity of labor market regulation in French civil law countries, where the basic regulatory style is vulnerable to political pressures. We also present some indirect evidence that the older workers, and those more likely to be covered by the laws, are the likely

beneficiaries, and hence political supporters, of labor regulation. But politics plays the second fiddle; the main determinant of the regulatory style is the historical origin of a country's laws.

This finding echoes our earlier results on the regulation of entry and on the formalism of judicial procedures. These findings also showed that countries from different legal origins rely on different institutional technologies for social control of business. A key result in the present paper is the high correlation among our measures of regulation of different activities across countries: countries that regulate entry also regulate labor markets and judicial proceedings. The bottom line of this research is the centrality of institutional transplantation: countries have regulatory styles that are pervasive across activities and shaped by the origin of their laws.

**Table I**  
**Description of the variables**

The table describes the variables in the paper. Unless otherwise specified, the sources for the variables are the laws of each country.

Variable	Description
<i>Employment laws</i>	
<i>Alternative employment contracts</i>	
Part-time employment is prohibited	We define a ' <i>part-time worker</i> ' as any employee working 20 hours per week. It includes people working 4 hours per day 5 days per week, and people working full time two and a half days per week. The second case is frequently known as a ' <i>temporary worker</i> '. This variable equals one if part-time employment is prohibited by the labor laws. Equals zero if part-time work is expressly allowed or if labor laws are silent thereon.
Part-time workers are not exempt from mandatory benefits of full-time workers	Equals one if a part-time worker working half the time of a full-time worker enjoys at least half of the benefits enjoyed by the full-time worker. The variable is also equal to one if part-time employment is prohibited by the labor laws. The variable equals zero if part-time workers are not entitled to: (i) at least half of the maximum hours of work, leaves, and overtime premiums; (ii) social security coverage (pensions, health, unemployment); or (iii) if there are entitlement thresholds of more than half the legally mandated regular work week for premiums, leaves, or social security coverage. In countries where there are minimum-earnings thresholds to obtain benefits (rather than time-based thresholds), the analysis is done considering a salary equal to half of the country's GNP per worker.
It is not easier or less costly to terminate part-time workers than full-time workers	Equals one if part-time workers working half time enjoy at least half of the legal rights to advance notice and separation fees for the termination of the employment contract of full time workers. Equals zero otherwise.
Part-time contracts	Measures the protection of part-time workers in the labor law as the average of the preceding three variables.
Fixed-term contracts are only allowed for fixed-term tasks	The term ' <i>fixed-term contract</i> ' refers to workers employed for fixed periods of weeks, months, or years. In many countries a person working for two or three days per week is considered a fixed-term, rather than a part-time, worker. This variable equals one if fixed-term contracts are allowed only: (i) for jobs that are temporary by nature; (ii) for temporary vacancies to replace a permanent worker in maternity or sickness leave; (iii) for training contracts; (iv) for seasonal work; and/or (v) if the law expressly states that the will of the parties involved in the contract is not a good enough reason for entering into a fixed-term contract. Equals zero otherwise.
Maximum duration of fixed-term contracts.	Measures the maximum cumulative duration of fixed-term contracts. The variable is normalized from 0 to 1, where higher values mean lower allowed duration of fixed-term contracts (higher protection). If there is no legally mandated ceiling or if fixed-term contracts may be renewed without limit, the variable equals zero. The highest observation in our sample is 96 months and the lowest observation is 0 months.
Fixed-term contracts	Measures the protection of workers through limits set in the use of fixed-term contracts as the average of the preceding two variables.
The employment of family members is not exempt from any aspect of the labor law	Equals one if the employment of family members enjoys the protection of labor law, or if labor law is silent regarding family members' employment. Equals zero if the employment of family members is not subject to maximum hours of work, leaves, overtime premiums, advance notice and severance payment, social security coverage, or non-salary benefits. This variable is coded without regard to our assumption on firm size.
Subindex: Alternative employment contracts	Measures whether the law allows alternatives to the standard employment contract as the average score of: (i) part-time contracts; (ii) fixed-term contracts; and (iii) the employment of family members is not exempt from any aspect of the labor law.
<i>Conditions of employment</i>	
Mandatory minimum daily rest	Measures the mandatory minimum daily rest. This variable is normalized from 0 to 1, where higher values mean higher duration of mandatory daily rest (higher protection). If there is no legally mandated ceiling, the variable equals zero. Legal limits may be defined either as mandatory minimum rest hours per day, or as mandatory maximum regular and overtime working hours per day. For the latter case, we subtract this number from 24 hours in a day to obtain the equivalent of the minimum of rest hours per day. The highest observation in our sample is 14 hours and the lowest observation is 5 hours, excluding the countries that have no limit.

Variable	Description
Maximum number of hours in a regular work week	Measures the maximum duration of the regular work week (excluding overtime). This variable is normalized from 0 to 1, where higher values mean less hours of work (higher protection). If there is no legally mandated limit, the variable equals zero. The highest observation in our sample is 52 hours and the lowest observation is 37 hours.
Premium for overtime work	Measures the premium for overtime work, as defined by the law or mandatory collective agreement. This variable is normalized from 0 to 1, where higher values mean higher premium (higher protection). If the law provides for a variable schedule of overtime premium, we code the basic premium for the first hour of overtime. The highest observation in our sample is 100% and the lowest observation is 0%.
There are restrictions on night work	Equals one if by law or mandatory collective agreement: (i) there are restrictions on the maximum number of hours of work that can be performed at night; and/or (ii) if there are specific premiums for night-time work. Equals zero if night-time work is not subject to express limitations, i.e., if it is only subject to the general restrictions on the maximum length of the work day or work week, and the regular overtime premium. To code this variable we only consider specific regulations of night-time work and ignore regulations of work-shifts.
There are restrictions on "weekly holiday" work	Equals one if by law or mandatory collective agreement there are restrictions on work during the weekly holiday (Friday, Saturday, or Sunday, depending on the country). Restrictions include: (i) complete prohibition; (ii) express designation of a certain day of the week as weekly holiday, which the employer cannot change without workers' consent; (iii) specific maximum hours of work on such day; and (iv) special premiums for work on such day. Equals zero if work during the weekly holiday is: (i) allowed without restriction; or (ii) is only subject to the general limitations on the maximum length of the work week or work day and does not entail higher than regular overtime premiums.
Hours of work	Measures the protection of the regulation of hours of work as the average of the preceding five variables.
Days of annual leave with pay in manufacturing	Measures the length of the annual paid leave in manufacturing after twenty years of employment. This variable is normalized from 0 to 1, where higher values mean longer annual paid leave (higher protection). Equals zero if there is no minimum by law or mandatory collective agreement. If annual leave entails less than full pay, the number of days are discounted proportionally. The highest observation in our sample is 30 days and the lowest is 0 days. We assume that 7 calendar days equal 5 working days.
Paid time-off for holidays is mandatory	Equals one if workers are granted paid time off for national or local holidays by law or mandatory collective agreement. Equals zero otherwise.
Statutory duration of maternity leave with 100% earnings	Measures the length of the statutory duration of maternity leave for normal delivery/birth of a normal child with 100% of earnings. The variable is normalized from 0 to 1, where higher values mean longer maternity leave (higher protection). Equals zero if maternity leave is unpaid. If payment is less than 100%, time is reduced proportionally. The highest observation in our sample is 12 months and the lowest observation is 0 months. Source: <i>ILO, Conditions of Work Digest, 1994</i> .
Leaves	Measures the protection of the regulation on leaves of absence as the average of the preceding three variables.
Mandatory minimum wage	Equals one if there is a mandatory minimum wage by law or mandatory collective agreement, and zero otherwise.
Conditions of employment in the constitution	Measures the degree to which the regulation of conditions of employment appears in the country's constitution. Equals one if a right to certain minimum conditions of employment is expressly granted by the constitution. Equals 0.67 if the minimum conditions of employment are described as a matter of public policy or public interest in the constitution (or mentioned within the chapter on rights). Equals 0.33 if conditions of employment are otherwise mentioned in the constitution. Equals zero otherwise.
Subindex: Conditions of employment	Measures the protection in the law of conditions of employment as the average of: (i) hours of work; (ii) leaves; (iii) mandatory minimum wage; and (iv) conditions of employment in the constitution.

Variable	Description
<i>Job security</i>	
It is unfair to terminate the employment contract without cause	Measures the parties' leeway to agree on the conditions of termination of the employment contract. Equals one: (i) if the employer may not terminate the employment contract without cause; (ii) if the termination without cause always entails a mandatory penalty; or (iii) if the law bans the parties to enter into employment contracts that may be terminated by either party entirely at will or with a simple advance notice without any mandatory penalty. Equals zero otherwise.
The law establishes a public policy list of "fair" grounds for dismissal	Equals one if the law establishes a public policy list of "fair" grounds for dismissal. Equals zero if there is no list of grounds for dismissal or if parties are allowed to contract out.
Redundancy is not considered a "fair" ground for dismissal	Equals one if redundancy (also known as retrenchment, termination for economic reasons, necessities of the company, or objective causes) is not considered a "fair" ground for dismissal by law, or if such dismissal always entails a mandatory penalty. Equals zero otherwise.
Protection of grounds for dismissal	Measures the protection of the rules on grounds for dismissal as the average of the preceding three variables.
The employer must notify a third party before dismissing a redundant employee	Equals one if, by law or mandatory collective agreement, the employer must notify a third party (labor union, workers' council or government agency) before dismissing a redundant worker. Equals zero if the employer may dismiss a worker without notifying a third party, or if the employer may contract out of the prohibition.
The employer needs the approval of a third party to dismiss a redundant worker	Equals one if, by law or mandatory collective agreement, the employer needs the approval of a third party (labor union, workers' council or government agency) to dismiss a redundant worker. Equals zero if the employer may dismiss a worker without the approval of a third party, or if the employer may contract out of the prohibition.
The employer must notify a third party prior to a collective dismissal	Equals one if, by law or mandatory collective agreement, the employer must notify a third party (labor union, workers' council, government agency) before dismissing more than one worker. Equals zero if the employer may dismiss more than one worker without notifying a third party, or if the employer may contract out of the prohibition.
The employer needs the approval of a third party prior to a collective dismissal	Equals one if, by law or mandatory collective agreement, the employer needs the approval of a third party (labor union, workers' council or government agency) prior to a collective (more than one worker) dismissal. Equals zero if the employer may dismiss more than one worker without third party approval, or if the employer may contract out of the prohibition.
The law mandates retraining or replacement prior to dismissal	Equals one if, by law or mandatory collective agreement, the employer must provide relocation or retraining alternatives for redundant employees prior to dismissal. Equals zero otherwise.
There are priority rules applying to dismissal or lay-offs	Equals one if, by law or mandatory collective agreement, there are priority rules applying to dismissal or lay-offs, i.e., in order to fire redundant employees, the employer must follow a specific order of seniority, marital status, number of dependants or other objective priority criteria. Equals zero otherwise.
There are priority rules applying to re-employment	Equals one if, by law or mandatory collective agreement, there are priority rules applying to re-employment. Equals zero if former redundant employees need not be considered for new positions (i.e. there are no priority rules for re-employment).
Protection of dismissal procedures	Measures the protection of collective dismissal procedures as the average of the preceding seven variables.
Legally mandated notice period	Measures the length of the mandatory notice period for the dismissal of one redundant worker in manufacturing after twenty years of employment. The variable is normalized from 0 to 1, where higher values mean longer notice (higher protection). Equals zero if there is no minimum notice period by law. The highest observation in our sample is 24 weeks and the lowest is 0 weeks.
Legally mandated severance payment	Measures the amount of mandatory severance payment (including mandatory indemnity) for the dismissal of one redundant worker after twenty years of employment in manufacturing. The variable is normalized from 0 to 1, where higher values mean higher amounts (higher protection). Equals zero if there is no severance payment by law. The highest observation in our sample is 28.5 months and the lowest is 0 months.
Notice and severance payment	Measures the protection of the notice period and the severance payment for the unilateral termination of the employment contract by the employer. This partial subindex is calculated as the average of the preceding two variables.

Variable	Description
Right to job security in the constitution	Measures the presence of rules on termination of the employment contract in the country's constitution. Equals one if a right to job security or to the stability in the employment relation is expressly granted by the constitution. Equals 0.67 if job security is described as a matter of public policy or public interest (or mentioned within the chapter on rights). Equals 0.33 if job security is otherwise mentioned in the constitution. Equals zero otherwise.
Subindex: Job security	Measures the protection of the rules governing the termination of the employment contract as the average of: (i) protection of grounds for dismissal; (ii) protection of dismissal procedures; (iii) notice and severance payment; and (iv) right to job security in the constitution.
Index: Employment laws	Measures the protection of labor and employment laws as the aggregate sum of the: (i) subindex of alternative employment contracts; (ii) subindex of conditions of employment; and (iii) subindex of job security.
<i>Industrial (collective) relations laws</i>	
<i>Collective bargaining</i>	
Employers have the legal duty to bargain with unions	Equals one if employers have the legal duty to bargain and/or to reach an agreement with unions, workers councils or other organizations of workers. Equals zero if employers may lawfully refuse to bargain with workers. The variable only measures the duty to bargain, as opposed to the duty to bargain in good faith.
Collective contracts are extended to third parties by law	Equals one if the law extends collective contracts to third parties at the national or sectoral level. Extensions may be automatic or subject to governmental approval. Equals zero if collective contracts may not be extended to non-signatory workers or unions, or if collective contracts may be extended only at the plant level. Mandatory administrative extensions of collective contracts are coded as equivalent to mandatory extensions by law.
Law allows closed shops	Equals one if the law allows closed shops, and zero otherwise. Closed shops are agreements providing for mandatory union membership, which are binding on non-signatory and new employees. Union security legislation in general includes the following measures: (1) pre-entry closed shops, where workers have to belong to a union prior to taking up a job; (2) post-entry closed shops (or union shops), where workers are forced to join a union after taking up a job; and (3) absolute preferences, where an employer has to give a job to a union member if equally qualified to another non-union candidate. We do not consider post-entry closed shops.
Labor union power	Measures the statutory protection of unions as the average of the preceding three variables.
Right to unionization in the constitution	Measures the protection of the right to form labor unions in the country's constitution. Equals one if a right to form labor unions is expressly granted by the constitution. Equals 0.67 if labor unions are described as a matter of public policy or public interest (or mentioned within the chapter on rights). Equals 0.33 if labor unions are otherwise mentioned in the constitution. Equals zero otherwise.
Right to collective bargaining in the constitution	Measures the protection of the right to collective bargaining or the right to enter into collective labor contracts in the country's constitution. Equals one if a right to collective bargaining is expressly granted by the constitution. Equals 0.67 if collective bargaining is described as a matter of public policy or public interest (or mentioned within the chapter on rights). Equals 0.33 if collective bargaining is otherwise mentioned in the constitution. Equals zero otherwise.
Subindex: Collective bargaining	Measures the legal protection of the right to unionization and collective bargaining as the average of: (i) labor union power; (ii) right to unionization in the constitution; and (iii) right to collective bargaining in the constitution.
<i>Worker participation in management</i>	

Variable	Description
Workers and/or unions have a right to appoint members to the boards of directors	Equals one if the law gives workers and/or unions the right to appoint members to the Boards of Directors of individual companies, and zero otherwise. This arrangement is usually associated with the “German” model of co-determination.
Workers councils are mandated by law	Equals one if workers councils, committees or equivalent bodies are mandated by law. Equals zero if workers councils are not regulated by law or if their creation is voluntary for the employer. Workers councils are institutions of employers and workers created for the discussion of company’s policies affecting workers at the company level. This arrangement is sometimes called the “Swedish” model. The employer still has the sole right to decide on the operations of the company, but must negotiate and decide all matters affecting workers within the framework of workers councils.
Worker participation by law	Measures the statutory rights of workers to participate in the management of the companies as the average of the preceding two variables.
Right to participation in management in the constitution	Measures the protection of the workers' right to participation in management in the country's constitution. Equals one if a right to participation in management is expressly granted by the constitution. Equals 0.67 if participation in management is described as a matter of public policy or public interest (or mentioned within the chapter on rights). Equals 0.33 if participation in management is otherwise mentioned in the constitution. Equals zero otherwise.
Subindex: Worker participation in management	Measures the legal rights of workers to participate in the management of companies as the average of: (i) worker participation by law; and (ii) right to worker participation in management in the constitution.
<i>Collective disputes</i>	
Workers have the right to strike	Equals one if the laws grant workers the right or the freedom to strike, and zero otherwise.
Wildcat strikes are legal	Equals one if wildcat strikes are legal, and zero otherwise. Wildcat strikes are strikes not authorized by the labor union or the assembly of workers.
Political strikes are legal	Equals one if political strikes are legal, and zero otherwise. Political strikes are defined as strikes for political reasons or to protest government's policy, i.e., non work-related issues.
Sympathy / solidarity / secondary strikes are legal	Equals one if the law allows sympathy, solidarity or secondary strikes used to force decisions affecting workers other than those joining the strike, and zero otherwise. Sympathy or solidarity strikes are strikes by union members or workers who have no grievances against their employer, but who want to show solidarity with another union or workers. Secondary strikes are those against another employer who has business dealings with the employer involved in a dispute with the union or workers.
Legal strikes	Measures the protection of the right to strike in the law as the average of the preceding four variables.
No mandatory waiting period or notification requirement before strikes can occur	Equals one if by law there is no mandatory waiting period or notification requirement before strikes can occur, and zero otherwise.
A strike is not illegal even if there is a collective agreement in force	Equals one if a strike is not illegal even if there is a collective agreement in force, and zero otherwise.
Laws do not mandate conciliation procedures before a strike	Equals one if laws do not mandate conciliation procedures or other alternative-dispute-resolution mechanisms (other than binding arbitration) before the strike, and zero otherwise.
Procedural restrictions to strikes	Measures the absence of procedural restrictions to the right to strike in the law as the average of the preceding three variables.
Employer lockouts are not allowed	Equals one if employers' lockouts (strikes by employers) are not allowed, and zero otherwise. Lockouts may be offensive (when they are not provoked by workers) or defensive.

Variable	Description
Employers are not allowed to fire or replace striking workers	Equals one if the law prohibits employers to fire striking workers or to hire replacement labor to maintain the plant in operation during a non-violent and non-political strike. Equals zero otherwise.
Employer defenses	Measures the powers of employers during a collective dispute as the average of the preceding two variables.
Compulsory third party arbitration during a labor dispute is mandated by law	Equals one if the parties to a labor dispute are legally required to seek third party arbitration or the government is always entitled to impose compulsory arbitration on them. Equals zero otherwise. The term 'compulsory arbitration' refers to arbitration of private disputes against the will of the parties. It may protect workers by granting them an alternative to costly strikes in case of deadlocks in the negotiation process, but it may also limit the workers' right to strike.
Right to industrial action in the constitution	Measures the protection of the right to industrial action (i.e. strike, go-slow or work-to-rule) in the country's constitution. It equals one a right to industrial action is expressly granted by the constitution. Equals 0.67 if strikes are described as a matter of public policy or public interest (or mentioned within the chapter on rights). Equals 0.33 if strikes are otherwise mentioned in the constitution. Equals zero otherwise.
Subindex: Collective disputes	Measures the protection of workers during a collective dispute as the average of: (i) legal strikes; (ii) procedural restrictions to strikes; (iii) employer defenses; (iv) compulsory third party arbitration during a labor dispute; and (v) right to industrial action in the constitution.
Index: Industrial (collective) relations laws	Measures the protection of industrial (collective) relations laws as the sum of the: (i) subindex of collective bargaining; (ii) subindex of worker participation in management; and (iii) subindex of collective disputes.
<i>Social security laws</i>	
<i>Old age, disability and death benefits</i>	
The Social Security system covers the risk of old age, disability and death	Equals one if the social security system covers the risk of old age, disability and death, and zero otherwise.
Difference between retirement age and life expectancy	Measures the difference between the minimum legal age for normal retirement and the country's life expectancy at birth. This variable is normalized from 0 to 1, where higher values mean higher post-retirement life expectancy (higher protection). Normal retirement is the legally defined age for retirement with standard pension, and it excludes voluntary early or late retirement schemes. Equals zero if life expectancy is lower than retirement age. The highest observation in our sample is 23.8 years and the lowest is 0 years. Source: constructed using data from the laws of each country and the <i>Human Development Report, 1997</i> .
Months of contributions or employment required for normal retirement by law	Measures the number of months of contributions or employment legally required for normal retirement. The variable is normalized from 0 to 1, where higher values mean less contribution (higher protection). The highest observation in our sample is 540 months and the lowest is 0 months. Normal retirement is the legally defined age for retirement with standard pension, and it excludes voluntary early or late retirement schemes. If the law requires the worker to have a combination of certain number of months of work and a different number of months of contributions, we use the higher of the two figures since this is the one that is binding. Lump-sum and private pension systems do not define the number of months of contributions for normal retirement by law. In such cases, the amount of the pension solely depends on the number of months of contributions, thus we assume twenty years of contributions for normal retirement.
Percentage of the worker's monthly salary deducted by law to cover old-age and disability benefits	Measures the share of the worker's monthly salary deducted by law to cover old-age, disability, and death benefits. The variable is normalized from 0 to 1, where higher values mean lower deductions (higher protection). If the risk of disability and death is not included in the contribution for old-age pension, we add the individual components. The highest observation in our sample is 20% and the lowest is 0%. In some countries the social security contribution for old age, disability and death benefits also covers sickness and health benefits and/or unemployment benefits. In such cases, we calculate the share of contributions for each benefit for the average country in our sample, and apportion the total contribution among the several risks covered accordingly.

Variable	Description
Percentage of the pre-retirement salary covered by the old-age cash-benefit pension	This variable is the equivalent to the "replacement rate", which is the percentage of the pre-retirement salary covered by the average old-age cash-benefit pension. The variable is normalized from 0 to 1, where higher values mean higher percentage (higher protection). The highest observation in our sample is 90% and the lowest is 0%. For the countries that provide workers more than 12 pension payments a year, we add up the amount of all the payments and divided the total by 12 to get the equivalent "monthly" cash benefit pension. Where the pension plan provided for fixed monthly payments, rather than a percentage, the replacement rate is calculated using a pre-retirement salary equal to the country's GNP per worker. For lump-sum systems, where at the time of retirement a one-time payment is made equal to the worker's contributions plus accrued interest, the monthly old-age cash-benefit pension is calculated using the lump-sum payment divided by the difference between the average life expectancy and retirement age in months. As in the case of fixed monthly payment systems, the pre-retirement salary is calculated to be equal to the country's GNP per worker. The interest used in the calculation is the average monthly Libor rate over the previous ten years. The same methodology as in the lump-sum systems is applied to the private pension systems. If there are more than 12 pension payments per year we adjust the percentage accordingly.
Subindex: Old age, disability and death benefits	Measures the level of old age, disability and death benefits as the average of the preceding four variables.
<i>Sickness and health benefits</i>	
The social security system covers the risk of sickness	Equals one if the social security system covers the risk of sickness and zero otherwise.
Months of contributions or employment required to qualify for sickness benefits by law	Measures the number of months of contributions or employment legally required to qualify for sickness benefits. The variable is normalized from 0 to 1, where higher values mean less contribution (higher protection). If the law requires the worker to have a combination of certain number of months of work and a different number of months of contributions, we use the higher of the two figures since this is the one that is binding. The highest observation in our sample is 12 months and the lowest is 0 months.
Percentage of the worker's monthly salary deducted by law to cover sickness and health benefits	Measures the share of the worker's monthly salary deducted by law to cover sickness and health benefits. The variable is normalized from 0 to 1, where higher values mean lower deductions (higher protection). If the risks of sickness and health demand separate contributions, we add the individual components. The highest observation in our sample is 11.8% and the lowest observation is 0%. In some countries the social security contribution for old age, disability and death benefits also covers sickness and health benefits and/or unemployment benefits. In such cases, we calculate the share of contributions for each benefit for the average country in our sample, and apportion the total contribution among the several risks covered accordingly.
Waiting period for sickness benefits	Measures the waiting period for obtaining sickness cash benefits from the first day of sickness. The variable is normalized from 0 to 1, where higher values mean lower waiting periods (higher protection). The waiting period is the number of days before a person is legally entitled to receive sickness benefits. The highest observation in our sample is 42 days and the lowest observation is 0 days.
Percentage of the salary covered by sickness cash benefits for a two-month sickness spell	Measures the percentage of the salary covered by the average sickness cash benefit for a two-month sickness spell. The variable is normalized from 0 to 1, where higher values mean higher percentage of salary covered (higher protection). If sickness benefits last less than 2 months, the percentage of the salary by sickness benefits is discounted proportionally. The highest observation in our sample is 100% and the lowest observation is 0%. Sickness cash benefits are defined in some countries as a fixed amount in local currency, rather than as a percentage. In such cases, the percentage of the salary covered is calculated based on a salary equal to the country's GNP per worker.
Subindex: Sickness and health benefits	Measures the level of sickness and health benefit as the average of the preceding four variables.
<i>Unemployment benefits</i>	
The Social Security system covers the risk of unemployment	Equals one if the social security system covers the risk of unemployment, and zero otherwise.
Months of contributions or employment required to qualify for unemployment benefits by law	Measures the number of months of contributions or employment legally required to qualify for unemployment benefits. The variable is normalized from 0 to 1, where higher values mean less contribution (higher protection). If the law requires the worker to have a combination of certain number of months of work and a different number of months of contributions, we use the higher of the two figures since this is the one that is binding. The highest observation in our sample is 120 months and the lowest observation is 0 months.

Variable	Description
Percentage of the worker's monthly salary deducted by law to cover unemployment benefits	Measures the share of the worker's monthly salary deducted by law to cover unemployment benefits. The variable is normalized from 0 to 1, where higher values mean lower deductions (higher protection). The highest observation in our sample is 6.1% and the lowest observation is 0%. In some countries the social security contribution for old age, disability and death benefits also covers sickness and health benefits and/or unemployment benefits. In such cases, we calculate the share of contributions for each benefit for the average country in our sample, and apportion the total contribution among the several risks covered.
Waiting period for unemployment benefits	Measures the waiting period for obtaining unemployment benefits from the first day of unemployment. The variable is normalized from 0 to 1, where higher values mean lower waiting periods (higher protection). The waiting period is the number of days before a person is legally entitled to receive unemployment benefits. The highest observation in our sample is 70 days and the lowest observation is 0 days.
Percentage of the salary covered by unemployment benefits in case of a one-year unemployment spell	Measures the percentage of the salary covered by unemployment benefits for in case of a one-year unemployment spell. The variable is normalized from 0 to 1, where higher values mean higher percentage of salary (higher protection). If the maximum the duration of benefits is less than one year, the percentage of the annual salary is discounted proportionally. The highest observation in our sample is 90% and the lowest observation is 2.78%. Unemployment benefits are defined in some countries as a fixed amount in local currency, rather than as a percentage. In such cases, the percentage of the salary covered is calculated based on a salary equal to the country's GNP per worker.
Subindex: Unemployment benefits	Measures the level of unemployment benefits as the average of the preceding four variables.
Average of dummies on coverage of old age, sickness and unemployment	Equals the average of the three dummy variables for the existence of coverage, namely: (i) social security system covers the risk of old age, disability and death; (ii) social security system covers the risk of sickness and health; and (iii) social security system covers the risk of unemployment.
Index: Social security laws	Measures social security benefits as the sum of the: (i) subindex of old age, disability and death benefits; (ii) subindex of sickness and health benefits; and (iii) subindex of unemployment benefits.

---

*Left power*

Chief Executive's party has left or center political orientation	Measures the percentage of years between 1975 and 1995 during which the party of the country's chief executive had left or center orientation. If the country was not independent in the initial year of the period, we calculate the variable for the number of years since it became independent. For the countries that were part of a larger country in the initial year of the period and subsequently broke-up, we consider the political orientation of the larger country until the breakup. In the case of military regimes, where political affiliations are unclear, we classify the regime based on its policies. Source: <i>Authors' calculations based on descriptions and classifications in: Political Handbook of the World, Europa Yearbook, Statesmen database</i> < <a href="http://www.worldstatesmen.org">http://www.worldstatesmen.org</a> >, <i>Country Reports History</i> < <a href="http://www.countryreports.org">http://www.countryreports.org</a> >, Beck, Clarke, Groff, Keefer and Walsh [2001], various regional and country sources.
Largest party in congress has left or center political orientation	Measures the percentage of years between 1975 and 1995 during which the largest party in congress had left or center orientation. If the country was not independent in the initial year of the period, we calculate the variable for the number of years since it became independent. For the countries that were part of a larger country in the initial year of the period and subsequently broke-up, we consider the political orientation of the larger country until the breakup. In the case of military regimes, where political affiliations are unclear, we classify the regime based on its policies. Source: <i>Authors' calculations based on descriptions and classifications in: Political Handbook of the World, Europa Yearbook, Statesmen database</i> < <a href="http://www.worldstatesmen.org">http://www.worldstatesmen.org</a> >, <i>Country Reports History</i> < <a href="http://www.countryreports.org">http://www.countryreports.org</a> >, Beck, Clarke, Groff, Keefer and Walsh [2001], various regional and country sources.

Variable	Description
Chief Executive and largest party in congress have left or center political orientation	Measures the percentage of years between 1975 and 1995 during which both the party of the chief executive and the largest party in congress had left or center orientation. If the country was not independent in the initial year of the period, we calculate the variable for the number of years since it became independent. For the countries that were part of a larger country in the initial year of the period and subsequently broke-up, we consider the political orientation of the larger country until the breakup. In the case of military regimes, where political affiliations are unclear, we classify the regime based on its policies. Source: <i>Authors' calculations based on descriptions and classifications in: Political Handbook of the World, Europa Yearbook, Statesmen database</i> < <a href="http://www.worldstatesmen.org">http://www.worldstatesmen.org</a> >, <i>Country Reports History</i> < <a href="http://www.countryreports.org">http://www.countryreports.org</a> >, <i>Beck, Clarke, Groff, Keefer and Walsh [2001]</i> , various regional and country sources.
Union density	Measures the percentage of the total work force affiliated to labor unions. Source: <i>ILO, Laborsta</i> < <a href="http://laborsta.ilo.org">http://laborsta.ilo.org</a> >, and <i>The World Bank</i> .
Percentage of the labor force covered by collective agreements	Measures the percentage of the total labor force covered by collective agreements. Source: <i>ILO, Laborsta</i> < <a href="http://laborsta.ilo.org">http://laborsta.ilo.org</a> >, and <i>The World Bank</i> .
<i>Political and economic constrains</i>	
Constraints on executive power	Index of constraints on the executive power based on the number of effective veto points in a country. Veto points include: (i) an effective legislature (represents two veto points in the case of bicameral systems); (ii) an independent judiciary; and (iii) a strong federal system. Average of the years 1945 through 1998. Source: <i>Henisz [2000]</i> .
Effectiveness of legislature	Index of the effectiveness of the legislature. Ascending scale from 1 to 4 (1=no legislature; 2=largely ineffective; 3=partly effective; 4=effective). Average of the years 1945 through 1998. Source: <i>The Cross-National Time-Series Data Archive</i> < <a href="http://www.databanks.sitesting.net/www/main.htm">http://www.databanks.sitesting.net/www/main.htm</a> >.
Autocracy	The "general closedness of political institutions." Scale from 0 to 10, with 0 being low in autocracy and 10 being high in autocracy. Average of the years 1945 through 1998. Source: <i>Jagers and Marshall, [2000]</i> .
Actual openness	Trade share as a proportion of GDP in 1985 calculated using bilateral trade data. Source: <i>Frankel and Romer [1999]</i> .
Geographic openness	Trade share as a proportion of GDP in 1985 calculated using bilateral trade data and adjusted by the geographic component of each country's overall trade share. The geographic component of a country's trade is the sum of the estimated geographic components of its bilateral trade with the rest of the countries in the world. Source: <i>Frankel and Romer [1999]</i> .
Factor accumulation openness	Trade share as a proportion of GDP in 1985 calculated using bilateral trade data and adjusted by the country's rates of factor accumulation. Source: <i>Frankel and Romer [1999]</i> .
<i>Outcomes</i>	
Size of the unofficial economy	Size of the shadow economy as a percentage of GDP (varying time periods). Source: <i>Authors' calculations based on averaging all estimates reported in Schneider and Enste (2000) for any given country, as well as Sananikone [1996] for Burkina Faso, Chidzero [1996] for Senegal, Turnham and Schwartz [1990] for Indonesia and Pakistan, and Kasnakoglu and Yayla [2000] for Turkey.</i>
Employment in the unofficial economy	Share of the total labor force employed in the unofficial economy in the capital city of each country as a percent of the official labor force. Figures are based on surveys and, for some countries, on econometric estimates. Source: <i>Schneider [2000] and the Global Urban Indicators Database [2000]</i> < <a href="http://www.urbanobservatory.org/indicators/database">http://www.urbanobservatory.org/indicators/database</a> >.
Male participation rate in the labor force 1990-1994	Male participation rate as a percentage of the total male population aged 15 to 64. Based on population censuses or household surveys. Source: <i>Forteza and Rama [2000]</i> .
Female participation rate in the labor force 1990-1994	Female participation rate as a percentage of the total female population aged 15 to 64. Based on population censuses or household surveys. Source: <i>Forteza and Rama [2000]</i> .
Unemployment rate 1991-2000	Average unemployment rate as a percentage of the total labor force during 1991-2000. Source: <i>Laborsta</i> < <a href="http://laborsta.ilo.org">http://laborsta.ilo.org</a> >.

Variable	Description
Unemployed males 20-24 years old / active males 20-24 years old 1991-2000	Unemployed males aged 20 to 24 as a percentage of the total active male population of the same age during 1991-2000 period. Source: <i>Laborsta</i> < <a href="http://laborsta.ilo.org">http://laborsta.ilo.org</a> >.
Unemployed females 20-24 years old / active females 20-24 years old 1991-2000	Unemployed females aged 20 to 24 as a percentage of the total active female population of the same age during 1991-2000. Source: <i>Laborsta</i> < <a href="http://laborsta.ilo.org">http://laborsta.ilo.org</a> >.
Average wages of machine operators / wages of clerks and workers in craft and related trades 1990-1999	Average wages of machine operators across industries over those of clerks and workers in craft and related trades for the period 1990 to 1999. We use all 12 types of machine operators in the database including: (1) cloth weaver, (2) sewing-machine operator, (3) clicker cutter, (4) shoe sewer, (5) paper-making-machine operator, (6) machine compositor, (7) bookbinder, (8) mixing- and blending-machine operator (manufacture of industrial chemicals), (9) mixing- and blending-machine operator (manufacture of other chemical products), (10) metal-working machine setter, (11) machinery fitter-assembler and (12) card- and tape-punching-machine operator. The clerks and workers in craft and related trades we use are: (1) butcher, (2) building electrician, (3) bricklayer, (4) automobile mechanic and (5) stenographic typist (wholesale trade). To construct the variable we: (1) calculate individual wage ratios for each pair of machine operators and workers in craft, related trades and clerks for each year; (2) average each of these ratios across the 1990-1999 period to obtain the average relative wages for each pair of professions during the decade; finally (3) calculate the country average across all pairs of professions where machine operators are always the numerator and workers in craft and related trades or clerks are the denominator. Source: <i>Freeman and Oostendorp [2000]</i> .
<i>Other Variables</i>	
Log of GNP per capita	Logarithm of GNP per capita in 1997, Atlas method, expressed in current US dollars. Source: <i>World Development Indicators</i> .
Legal origin	Identifies the legal origin of the company law or commercial code of each country (English, French, Socialist, German, Scandinavian). Source: <i>La Porta et al. [1999]</i> .
Court formalism index for the eviction of a non-paying tenant	The index measures substantive and procedural statutory intervention in judicial cases at lower-level civil trial courts, and is formed by adding up the following indices: (i) professionals vs. laymen, (ii) written vs. oral elements, (iii) legal justification, (iv) statutory regulation of evidence, (v) control of superior review, (vi) engagement formalities, and (vii) independent procedural actions. The index ranges from 0 to 7, where 7 means a higher level of control or intervention in the judicial process. Source: <i>Djankov et al. [2003]</i> .
Court formalism index for the collection of a bounced check	The index measures substantive and procedural statutory intervention in judicial cases at lower-level civil trial courts, and is formed by adding up the following indices: (i) professionals vs. laymen, (ii) written vs. oral elements, (iii) legal justification, (iv) statutory regulation of evidence, (v) control of superior review, (vi) engagement formalities, and (vii) independent procedural actions. The index ranges from 0 to 7, where 7 means a higher level of control or intervention in the judicial process. Source: <i>Djankov et al. [2003]</i> .
Ln number of steps to start a business	Logarithm of the number of different procedures that a start-up has to comply with in order to obtain a legal status, i.e. to start operating as a legal entity. Source: <i>Djankov et al. [2002]</i> .
Ln number of days to start a business	Logarithm of the time it takes to obtain legal status to operate a firm, in business days. A week has five business days and a month has twenty two. Source: <i>Djankov et al. [2002]</i> .
Ln cost to start a business / GDP per capita	Logarithm of the cost of obtaining legal status to operate a firm as a share of per capita GDP in 1999. It includes all identifiable official expenses (fees, costs of procedures and forms, photocopies, fiscal stamps, legal and notary charges, etc). The company is assumed to have a start-up capital of ten times per capita GDP in 1999. Source: <i>Djankov et al. [2002]</i> .

**Table II**  
**Employment laws and industrial (collective) relations laws by GNP per capita**

The table classifies countries by GNP per capita and shows the Employment laws index, the Industrial (collective) relations laws index, and their respective subindices. The components of each subindex are not included in the table but can be found at <http://iicg.som.yale.edu/>. All the variables are described in Table I.

Countries	Employment laws				Industrial (collective) relations laws			
	Subindex: Alternative employment contracts	Subindex: Conditions of employment	Subindex: Job security	Employment laws index	Subindex: Collective bargaining	Subindex: Worker participation in management	Subindex: Collective disputes	Industrial (collective) relations laws index
<i>Bottom 25 percentile of GNP per capita</i>

**Table III**  
**Social security laws by GNP per capita**

The table classifies countries by GNP per capita and shows the social security laws index and its subindices. The components of each subindex are not included in the table but can be found at <http://iicg.som.yale.edu/>. All the variables are described in Table I.

Countries	The Social security system covers the risk of old age, disability and death	Subindex: Old age, disability and death benefits	The social security system covers the risk of sickness	Subindex: Sickness and health benefits	The Social security system covers the risk of unemployment	Subindex: Unemployment benefits	Social security laws index

a=significant at 1 percent level; b=significant at 5 percent level; c=significant at 10 percent level.

\* The rows in the Political and economic constraints column consist of the values of: first row=constraints on executive power; second row=effectiveness of legislature; third row= autocracy; fourth row= actual openness; fifth row= geographic openness; sixth row= factor accumulation openness.

Table XI

## Interactions between legal origin and left political orientation: French vs English legal origins

Ordinary least squares regressions of the cross section of countries, excluding all socialist countries. The dependent variables are: (i) Employment laws in Panel A, and (ii) Industrial relation laws in Panel B. Each regression is separately run for French legal origin and English legal origin countries. For each pair of regressions, we run a Chow test of the equality of the estimated coefficients for French and English legal origins. Robust standard errors are shown in parentheses. All the variables are described in Table I and the data can be found in <http://iicg.som.yale.edu/>.

	Left or center party in power				N [R <sup>2</sup> ]	Chow test of the equality of coefficients

## Abstract

This paper studies the effect of mandated employer-provided child care on the wages of women hired in large firms in Chile. We use a unique employer-employee database from the country's unemployment insurance (UI) system containing monthly information for all individuals that started a new contract between January 2005 and March 2013. We estimate the impact of the program using regression discontinuity design (RDD) exploiting the fact that child care provision is mandatory for all firms with 20 or more female workers. The results indicate that monthly starting wages of the infra-marginal woman hired in a firm with 20 or more female workers are between 9 and 20 percent below those of female workers hired by the same firm when no requirement of providing child care was imposed.

**Keywords:** Mandated benefits, female wages, regression discontinuity, policies for gender equality.

This paper has benefitted from the discussion and comments from seminar participants at Western Economic International (San Francisco, 2012) and LACEA/LAMES (Sao Paulo, 2014). Sergio Urzúa is thankful for the support of the National Institute of Health (NICHD R01HD065436). The access to the Unemployment Insurance Database was possible thanks to the agreement between the Inter-American Development Bank and the Chilean Ministry of Labor and Social Protection. All the information utilized in this paper was kept anonymous and no individual indicators were used. The data was saved and managed in a secure server.

## 1 Introduction

One of the main characteristics of Chile's labor market is the low labor force participation of women. According to International Labor Organization (ILO) statistics for the period 2011-2013, Chile and Mexico have the lowest participation rate of women in Latin America.<sup>1</sup> The rate in Chile is also below the United States and the average rate for European countries by more than ten percentage points. The situation, however, has shown improvements over the past two decades, with the rate increasing from 31.8 in 1990 to 47.8 in 2012.<sup>2</sup>

Since the return to democratic governance at the end of the 1980s, Chile has formulated several public policies to reduce gender disparities in the labor market by stimulating female hiring, reducing discrimination, and promoting work and family balance (Henriquez and Riquelme, 2011). In the early 1990s, the government created the National Women Service -Servicio Nacional de la Mujer- an institution devoted to the promotion of equal opportunities for men and women in Chile. Since then, a number of laws and programs have been enacted to support women's rights and increase female access to the labor market.

One example is Article 203 of the Labor Code, which mandates that all firms with 20 or more female workers regardless of their age, marital status, or type of contract should provide a place near but independent from the workplace where mothers can leave their children under two years old during the workday and feed them as necessary.<sup>3</sup> The employer must offer the service in a separate facility near the workplace, pay an external provider directly, or provide additional compensation to the female employee to cover the expense. The government must approve all child care centers through its National Board of Daycare Centers (the Junta Nacional de Jardines Infantiles, or JUNJI). This law supports the mothers transition back to work, while promoting the close motherchild relationship and the healthy development of the child. It is well know that problems with securing and affording child care can create conflict in the workfamily balance, and to the extent that this can lead to lost work days, the choice to give up paid work temporarily, or

---

<sup>1</sup>LABORSTA database downloaded on December 1st 2014. We compared female labor force participation rates in Chile with those in the following countries: Argentina, Bolivia, Brazil, Colombia, Jamaica, Mexico, Panama, Paraguay, Peru, Uruguay, and Venezuela.

<sup>2</sup>According to the statistics presented in KILM/ILO 8th Edition, which are based on LABORSTA until 1995 and on OECD Labour force Statistics Database from then onward.

<sup>3</sup>The first law regulating the provision of child care to employees dates back to 1917 (Law 3186). Since then the law has been subject to several modifications (1993, 1995, 1998, 2002, 2007 and 2009), which are reflected in the current version of Article 203.

job loss, child care is implicated in reduced wages for mothers.

Aside from the potential positive impact of the policy on labor supply decisions, the immediate effect of the law is an increase in the cost associated with hiring and employing women. In fact, it creates a wedge between the labor costs of females and males, implying a new source of gender disparities. Standard economic theory suggests that the labor market effect of mandated legislation will be concentrated in employment with no change in wages. However, some effect on wages may be expected given the importance of child care in shaping employment decision of females.

The objective of this paper is to quantify the effect of the mandated employer-provided child care on the starting wages of women hired in large firms in Chile. The focus is on large firms because for small and medium firms compliance with the law is not high enough to obtain an accurate estimation of the wage adjustments made in response to the law. In particular, we concentrate on the wages of new female employees because the wage adjustment is more flexible in this case than for active workers.

We use a unique employer-employee database from the unemployment insurance (UI) system containing monthly information for all individuals that started a new contract between October 2002 and March 2013. We exploit the availability of longitudinal data to analyze the impact of the law on firm-specific new hires, those leading firms to cross the threshold of 20 female workers. Our results indicate that the policy has sizable effects on starting wages of women working in large firms created after 2005. Specifically, women hired in a firm with 20 or more female workers make CLP\$24,000 to CLP\$53,000 (approximately US\$39-US\$87) less than women hired when no requirement of providing child care was imposed (i.e., when firm has less than 20 female workers).<sup>4</sup>

The paper contributes to three strands of the literature. First, it informs on the effects of labor market regulations on wages, more precisely, on the effects of group-specific mandated benefits on group's wages. Identifying this pass-through is critical for understanding the efficacy of the policy. Second, the paper contributes to the debate on the unintended consequences of public policies in general and policies aimed to promote gender equality in particular. Third, the paper adds to the literature that analyzes the impact of non-linearities in legislation and their impact on labor market flexibility, especially those that have dynamic implications.

---

<sup>4</sup>Values are expressed in 2009 Chilean pesos. Values in dollars computed using the exchange rate in effect on April 2015 of 609.89 Chilean pesos per US dollar.

This paper offers a unique contribution to the recent analysis of the effect of mandated child care benefits in Chile. By using longitudinal data, it provides a precise estimate of the effect of the law on wages by following firms as they grow over time and compare individual wages within a firm before and after crossing the threshold. We discuss how the trivial comparison of firms above and below the threshold at a given point in time ignores fundamental differences across firms, which may bias the estimates in unpredictable ways.

The document is organized into seven parts. The second section summarizes the literature of the effects of mandatory legislation on the labor market. The third section describes the data used. The fourth section presents the conceptual framework. The fifth section explains in detail the empirical strategy of the paper. The sixth section presents the main results. Section seven concludes.

## 2 Effect of Mandatory Legislation on the Labor Market

Under the standard neoclassical labor demand-labor supply framework, mandatory legislation that increases labor costs reduces employment with no change in wages. This result is explained by the assumption of a perfectly elastic labor supply. Then, the cost is entirely paid by the employer. In the context of a not perfectly elastic supply of labor, however, part of the increase in labor costs will reduce wages, and thus, the effect on the labor market will be limited. In addition, the employee valuation of the benefit is important to determine its effect on wages and employment, since it determines whether workers accept lower wages when receiving mandated benefits.

Summers (1989) points out that “in terms of their allocational effects on employment, mandated benefits represent a tax at a rate equal to the difference between the employers cost of providing the benefit and the employee’s valuation”. Thus, in the limit and in the absence of asymmetric information between workers and firms, wage rigidity, or credit constraints, mandated benefits are borne by the workers in the form of lower wages, and have no effect on employment (e.g., Summers, 1989; Gruber and Krueger, 1991; Gruber, 1994). The extent to which the cost of mandatory legislation is translated into lower wages is an empirical question.

Several empirical papers provide evidence of a large effect of payroll taxes and mandated benefits on wages. For the United States Gruber and Krueger (1991) study the incidence of increases in the

cost of workers' compensation (referring specifically to insurance for workplace injuries) and find that 85 percent of the cost of the mandated employer-provided insurance shift to wages, with limited disemployment effect.

Similarly, Gruber (1994) analyzes the effects of mandated maternity benefits in the United States and, using a difference-in-difference estimation, finds that a large share of the cost is shifted to wages with only minor disemployment effects. In fact, Gruber finds that legislation causes young women's wages to fall by as much as 5 percent with no effect on their labor supply, suggesting a 100 percent pass-through rate.<sup>5</sup>

In the context of Latin America, most of the evidence uses the dramatic shifts in policy regimes that took place during the decade of reforms that started in the late 1980s and early 1990s. Heckman and Pagés (2004) present a comprehensive summary of the evidence on wage shifts for the region. In the case of Ecuador, they highlight the work of MacIsaac and Rama (1997), documenting that part of the increase in labor cost associated with mandated contributions to social security programs is shifted to workers in the form of lower base wages (i.e., the foundation on which benefits are paid). In fact, for an average cost of social security contributions and other mandated benefits that amounts at least 57 percent of the base wage, the authors find a 39 percent reduction in the base earnings of workers in firms that comply with these regulations compared with workers at non-compliant firms. Their empirical strategy consists in including a dummy variable that identifies compliant firms into the estimation of a wage equation using the Living Standards Measurement Study (LSMS) of 1994. The regression is performed on take-home wages and base wages controlling for individual variables (education, experience, gender, marital status, dummies for indigenous, urban and other geographical variables) and characteristics of the firm (dummies for modern, public, agriculture and unionization).

Mondino and Montoya (2004) analyze the effect of labor market regulations in Argentina during the period 1975-1996. Similar to MacIsaac and Rama (1997), they compare wages of workers who have access to social security programs with wages of uncovered workers; in the estimation of the wage equation, however, they control for the difference between the decision to participate in a job

---

<sup>5</sup>Not all empirical papers find evidence of large effects on wages. Baum (2003) finds little effect of maternity leave legislation on either employment rates or wages. He uses interstate variation in legislation and the Family and Medical Leave Act (FMLA) signed in 1993 by President Clinton. His results may be due to fact that the mandated leave is short and unpaid, and many employers provided maternity leave benefits prior to the statutes.

search and that of accepting a job offer. They find that the gross wages of non-covered workers were 8 percent higher than those of covered workers.

In the case of Mexico, Marrufo (2001) examines the effects of the 1997 pension reform. After decomposing the effect of the reforms into the effect of a tax reduction and the effect of tying benefits to contributions, Marrufo finds that wages absorb 43 percent of the increase in social security taxes and 57 percent of the value of benefits. She controls for self-selection and also accounts for general equilibrium effects to overcome the problems with the difference-in-difference estimates that understate the true extent of wage adjustment.

Finally, in the case of Chile, Gruber (1997) uses the sharp exogenous reduction in employer-paid labor taxes produced by the privatization of the social security system to estimate its effect on the labor market. Gruber's estimates point to a 100 percent pass-through rate. As Heckman and Pagés (2004) point out, there are several caveats for his estimates. First, with the decline in payroll taxes, workers' contributions also increased and if measured wage payments by firms include employee contributions, then the higher measured wages will capture not only the effect of lower employer-paid taxes but also the higher employee-paid contributions. Second, measurement errors in the wage bill and tax payments may bias the estimates toward full shifting.

Using data from the 1994's national survey of socioeconomic conditions (Encuesta de Caracterización Socioeconómica Nacional-CASEN), Edwards and Cox-Edwards (2000) analyze the effect of a social security reform on labor market outcomes in Chile. The authors estimate a wage equation controlling for the decision to contribute to the social security system. They find that take-home wages for workers covered by mandatory pension, health, and life insurance were 9 percent lower than wages for non-covered workers. Using the fact that in 1994 social security contributions amounted to 20 percent of wages and were nominally paid by workers, their estimates suggest that the workers absorbed about 45 percent of the cost of the contributions in the form of lower wages, while the other 55 percent fell on employers.

As previously stated, these estimates of large pass-through rates rely on the absence of asymmetric information between workers and firms, wage rigidity, or credit constraints. While these assumptions may hold at the top of the wage distribution, they are unlikely to be true at the bottom, which implies lower shifts of the costs to wages. One important factor in the context of Latin America is the downward wage rigidity at the bottom of the distribution; thus, it is cru-

cial for the analysis to evaluate whether minimum wage binds. For example, Maloney and Nunez (2004) document that the minimum wage binds in Colombia, which is consistent with the weak pass-through effects found by Cardenas and Bernal (2004) for the country. In the case of Chile, it will be interesting to determine whether the results of Gruber (1997) were driven by the fact that the minimum wage does not bind or by the specificity of the study.

However, some of the theoretical predictions for general mandates may not hold in the case of group-specific mandates, such as the one we are considering for Chile. Gruber (1994, 1997) points out that the scope for wage adjustment might be more limited due to barriers to adjust relative wages. In addition, even with barriers for wage shifting, these mandates may discourage hiring of new employees belonging to the specific group, as employers seek to hire workers with lower benefit costs, altering the dynamics of the labor market. Thus, mandated benefit programs might work against the interests of those who most require the benefit being offered.

Two other papers analyze the effect of child care mandated benefits in Chile. Escobar (2014) uses data from the annual survey of manufacturing firms -Encuesta Nacional Industrial Anual (ENIA)- covering the period 1995-2007 to estimate the effect of Article 203 on firm's hiring decisions. In particular, he assesses the extent to which firms substitute female labor with male labor or capital to avoid the cost associated with the law. He documents the presence of concentration of firms below the threshold of 20 female workers, and no effects of the law on average wages per worker. Unfortunately, unlike the data used in this paper, ENIA does not contain worker-level data and only gathers information on a specific sector. This prevents a disaggregated dynamic analysis of wages by gender, limiting the scope of the findings regarding the wage adjustment. Our results confirm these limitations.

Villena et al. (2015) use a cross sectional sample (October 2010) from the same data analyzed in this paper to estimate the effect of the same law on wages. They focus on firms with more than 5 and less than 35 female workers and restrict the analysis to three industries. Based on a regression discontinuity approach implemented in a static framework, they find that firms shift the cost of mandated child care benefits to all workers -both females and males. The estimated local static average effect is a 4 percent reduction in wages of active workers. The small magnitude of this effect contrasts to the large effects presented in our paper. Several reasons explain these differences. First, Villena et al. (2015) does not take into account the evidence of limited compliance with

the law among small and medium size firms. Second, their static empirical analysis ignores firm dynamics. As we show, high frequency hires and dismissals changing the position of the firm with respect to the threshold are extremely common in Chile. This affects the interpretation of the static findings. In this paper, we deal with this challenge by analyzing individual hires over time at the firm level.<sup>6</sup> Third, average effects obtained from cross-sectional variation across firms overlook the importance of firm heterogeneity. In contrast to the analysis of Villena et al. (2015), our dynamic set up controls for firm-specific fixed effects. To the best of our knowledge, this is the first paper addressing the impact of child care mandated benefits labor legislation taking into account both dynamic firm behavior and firm-level heterogeneity.

### 3 Data Description

The database from the country’s unemployment insurance (UI) system -Seguro de Cesantía- includes information on the demographic characteristics of individuals (e.g., age, gender, education, marital status) and their geographic location. It also contains information from the firms where the individuals work, such as salary history, type of contract, sector of activity, and hiring date. The size of the firm (number of workers) is computed by counting the number of registered workers in each firm. The employer collects the information and must submit it to the institution that administers the pension system in Chile (Administradora de Fondos de Cesantía, or AFC). This procedure is mandatory for all contracts that started after October 2, 2002. Workers that were already working before this date can enter voluntarily into the system. Once an individual is registered in the system, the information is updated on a monthly basis, even if the individual changes his or her employer.

Motivated by the nature of our main question and by some challenges of the data, we use a subsample of the firms that guarantees the accuracy of our estimates. We concentrate on *large and new firms*. Firms are classified as *large* if they employ 200 or more workers in a calendar year.<sup>7</sup> The definition of *new* is based on the date of creation, so firms are classified as new if they registered a new contract for the first time in 2005. As a result, the period of analysis is 2005-2013. Each

---

<sup>6</sup>For example, using data from the Chilean unemployment insurance (UI) system, we calculated that 40 percent of the firms with less than 20 female workers in a given month, eventually pass the threshold within a year. Furthermore, around 14 percent of these firms pass the threshold in the next month.

<sup>7</sup>We compute the number of workers per firm on an annual basis.

decision is related to some features of the data, so we present the arguments for the selection of the sample as a response to overcome three main challenges.

First, the data do not contain information on the actual provision of child care; this is an important challenge because there is no perfect compliance with the law. In a situation of perfect compliance, we could rely exclusively on the number of female workers to classify firms facing the obligation to pay for child care services from those not facing such an obligation.

To overcome this challenge, we restrict the analysis to *large* firms because these firms are more likely to observe the law than small and medium firms. According to the 2011 National Labor Survey (Encla 2011), 28 percent of firms with more than 20 female workers do not comply with the law to provide child care services, a figure concentrated mainly in small and medium firms. In contrast, 90 percent of large firms provide child care services to their employees Dirección del Trabajo (2012).<sup>8</sup> Also, large firms are subject to more stringent vigilance and control.

Columns 1 and 2 in Table 1 compare the sample of large firms with all the firms available in the data. Large firms represent less than 1 percent of all the firms in the data, but they are highly representative of the firms that are mandated to provide child care services to their employees.<sup>9</sup> Based on the 2008 National Labor Study (Encla, 2008), large firms comprise 63 percent of all firms complying to the law (Dirección del Trabajo, 2008).<sup>10</sup> In addition, as presented in Table 1, while only a very small fraction of the firms in the data crosses the threshold of having 20 female workers, 75 percent of large firms at some point cross the threshold between 2002 and 2013. For these firms, we observe the starting wages of all new female workers as the firm approaches the threshold. We exploit this feature of the data in our empirical approach.

[Table 1 about here.]

The second challenge of the UI data is the uncertainty about the total number of workers for some firms. Our data contain very rich information on all new contracts that started after October 2, 2002, when the law mandated that they be registered into the system. Workers with contracts before

---

<sup>8</sup>This percentage corresponds to firms that have 20 or more female workers and at least one with children at the eligible age range. The survey has detailed information on 3,153 firms 79,786 using sampling weights. The sample is representative by region and size of firm. The sample, which comes from the National Revenue Service, includes all the firms in the national territory that paid taxes in 2009. For more information, see Dirección del Trabajo (2012).

<sup>9</sup>70.31 percent of all the firms in the data have less than 5 workers; 13.3 percent have 5 to 9 workers; 12.8 percent have between 10 and 49 workers; and 2.7 percent have 50 and 199 workers.

<sup>10</sup>In 2008, the ENCLA had a specific module to analyze child care provision and compliance with the law.

October 2002 have not been automatically entered. They can, however, be entered voluntarily into the system. Consequently, there is no guarantee that the number of workers registered in the system coincides with the actual number of workers in each firm. To overcome the challenge created by the uncertainty in the total number of workers in general, and the total number of female workers in particular, we use only *new* firms.<sup>11</sup> We restrict the analysis to new firms because we can follow their expansion and have certainty that all workers are registered in the system and appear in the data. Finally, we compute the number of workers per firm on an annual basis. Each decision is related to some features of the data, so we present the arguments for the selection of the sample as a response to overcome three main challenges.

Columns 3 and 4 in Table 1 present basic descriptive statistics on new firms and firms that are both new and large. Our final sample uses information on new hires in this subsample of 1,912 firms. This selection of the sample reduces the external validity of our results in the sense that we are not including the complete universe of firms in Chile, but we gain confidence in the precision of our estimates.

The third challenge is the presence of large variations in the total number of workers in a firm within a year. Having monthly data is definitively an advantage for our study, but the registration process and actualization of the information do not necessarily coincide with the monthly frequency. In some cases the frequency mismatch responds to the typical timing of the registration process of registration for new employees (minimum 3 to 4 months). In other cases, it responds to the possibility of avoiding monthly actualization of the information in the system. In consequence, the number of employees recorded in the system in a given month may not coincide with the real number of workers in the firm.<sup>12</sup> To overcome this issue, we use the maximum number of workers observed in a year in each firm, as the variable that determines whether or not the firm is mandated to provide child care services to its employees.

Finally, since we are interested in comparing the wage of females in the margin as the firm

---

<sup>11</sup>The sample contains 525,181 new firms, which accounts for nearly 63 percent of the 837,899 firms in the sample.

<sup>12</sup>For example, when a new person is hired, employers must submit his or her information to the institution that administers the pension system in Chile (Administradora de Fondos de Censatias-AFC) within 10 days. Between the actual hiring date and the date the individual appears in the system, however, there is a window of three months (date of hiring, report the new employee, first payment, creation of account, and next wage). Regarding the actualization of information, it is possible that some individuals do not appear every month in the data due to a delay in paying the monthly contributions. In theory, once an individual is registered in the system, the information is updated on a monthly basis because the contributions must be paid every month. However there is a window of 90 days before firms have to pay the penalty fee associated with the delay.

approaches the threshold of 20 female workers, we restrict the analysis to the starting wage of each woman in each firm.<sup>13</sup> As a result, the outcome of interest is the wage offered to (and accepted by) a woman in a firm that is very close to having a total of 20 female workers. Ideally, we would like to analyze only the starting wage of the 20th female, since that is exactly the point of discontinuity. In reality, we are close to that ideal because the data include all new contracts that started after October 2002 and, by concentrating on new firms, we may be able to observe the hiring of the 20th female worker.

Table 2 presents the description of the data on females hired for the first time in large new firms. “N\_workers” is the average of the number of workers employed in the firm hiring new female workers over the period 2005-2013; “N\_female workers” is the average number of female workers employed in the firm where the individual was hired; the analogous is true for “N\_male workers”; “Starting wage” for female workers is the average of the real starting wage in Chilean pesos of 2009 for the females in the sample; “Average wage females/males firm” corresponds to the average wage of female or male workers working at the firm where the female was hired; “Above” is a dummy variable for the firms with twenty or more female workers: the number of observations corresponds to individual hires and “N\_firms” is the number of firms considered.

[Table 2 about here.]

## 4 Conceptual Framework: Firm’s Behavior at the Margin

One important consideration is the discontinuous nature of the policy. Unlike standard mandates, the increase in the labor costs associated with hiring females only activates when the firm reaches the threshold of 20 female workers. This section briefly discusses the behavior of the firm at the margin.

Assume the firm only has two inputs in production: female workers  $f$  and male workers  $m$ . The production function is described as follows:

$$Q = F(f, m; \theta)$$

---

<sup>13</sup>In this context, if one woman is hired by different firms, we include her as multiple observations of starting wages.

where  $\theta$  is a parameter that summarizes all other characteristics of the production process.

Given the prices of the inputs,  $w_f$  and  $w_m$ , the price taker firm maximizes profits. The first order conditions are:

$$w_f = F_f(f, m; \theta)$$

$$w_m = F_m(f, m; \theta)$$

As a result, the optimal allocation of workers given the relative prices is given by:

$$\frac{w_m}{w_f} = \frac{F_m(f, m; \theta)}{F_f(f, m; \theta)} \quad (1)$$

If the production function exhibits constant returns to scale, equation (1) can be expressed as follows:

$$\begin{aligned} \frac{w_m}{w_f} &= \frac{F_m(m/f, 1; \theta)}{F_f(1, m/f; \theta)} \\ &= \kappa(m/f; \theta) \\ &= \kappa(R; \theta) \end{aligned}$$

In this context, the policy affects the cost of female labor, acting as a tax. The wage of females in firms with 20 or more female workers will be  $\tilde{w}_f = w_f + \tau$ . In consequence, the optimal selection of inputs will be given by:

$$\frac{\tilde{w}_m}{w_f} = \kappa(\tilde{R}; \theta) \quad (2)$$

A firm with 19 female workers will experience a change in relative wages. In response, the profit maximizing behavior implies adjusting the optimal fraction of male to female workers, changing from  $R$  to  $\tilde{R}$ . Without the policy, the firm would continue increasing the scale of production without changing the optimal ratio of male to female workers  $R$ .

In the process of expansion, a firm in the margin faces two options to increase the scale of production. The first alternative is to substitute female workers with male workers, to avoid the change in relative prices implied by the policy (not hiring the 20th female worker). This option implies altering the optimal combination of inputs and, as a result, it has a direct impact on employment levels and is associated with the concentration of firms just before the before the

threshold is reached. This concentration is referred in the literature as “bunching”. The viability of this option, however, depends on the elasticity of substitution between female and male labor.

The second alternative is to hire the 20th female worker and pay the additional cost associated while maintaining the optimal ratio of male to female workers. In this paper, we are interested in quantifying the effect of the policy on female wages.

## 5 Empirical Framework: Sharp RDD with Firm-specific Fixed Effects

The empirical strategy employed in this paper is a “sharp” regression discontinuity design (RDD). This strategy is used to compute the causal effect of the legislation on the outcome of interest, i.e., the starting wage of women working in large firms in Chile between 2005 and 2013.

Using the basic setting for the Rubin Causal Model (RCM) the outcome observed can be written as:

$$w_i = \begin{cases} w_i(0) & \text{if } D_i = 0 \\ w_i(1) & \text{if } D_i = 1 \end{cases} = w_0(1 - D_i) + w_1 D_i$$

$$D_i = \mathbf{1}\{F_i \geq 20\}$$

where  $w_i(0)$  represents the wage for female workers without exposure to the treatment,  $D_i = 0$  (i.e., women working in firms with less than 20 female workers);  $F_i < 20$  and thus, not receiving child care services by their employers;  $w_i(1)$  is then the wage given exposure to the treatment, i.e., for women working in firms with 20 or more female workers and in consequence, receiving employer-paid child care services for their children under two years of age.

We are interested in the average causal effect of the treatment at the discontinuity point:

$$\tau = E[w_i(1) - w_i(0) | F_i = 20] \quad (3)$$

To determine the validity of our approach we need to ensure that at least four basic assumptions for RD are satisfied (see Nichols, 2007). The first assumption is that the treatment is not randomly assigned. This assumption is satisfied because only firms with 20 or more female workers are

mandated to provide child care services to their female employees, an observable variable. In addition, we restrict the analysis to large firms where the compliance to the law is high to ensure that provision of child care is a deterministic function of the number of women working at the firm.

The second assumption is the presence of a discontinuity in the wage of females when the number of female workers is 20, so the selection on observables at the threshold is also satisfied. Figure 1 presents the average of the starting wage for females by the number of women working at the firm where they were hired.<sup>14</sup>

[Figure 1 about here.]

The third assumption is that there is no manipulation of the running variable. Finally, the fourth assumption requires that the other variables -demographic characteristics and characteristics of the firm where the individual is employed- are smooth functions of the assignment variable conditional on treatment -that is, the only reason the outcome variable should jump at the threshold is due to the discontinuity in the level of treatment.

To discuss in detail the last two assumptions, we introduce some additional notation. In this case the running variable -number of female workers- is discrete so the conditions for non-parametric or semiparametric methods are not satisfied. Instead we regress  $w_{ij}$  on a low-order polynomial in  $F_{ij}$ . According to Lee (2008a) if the polynomial function correct the conventional ordinary least squares (OLS) inference is appropriate.<sup>15</sup>

$$w_{ij} = \alpha + G(\tilde{F}_{ij}) + D_i * G_p(\tilde{F}_{ij}) + \tau D_i + \gamma_j + \epsilon \quad (4)$$

$$\text{where } \tilde{F}_{ij} = F_{ij} - 20,$$

and  $G_p(\tilde{F}_{ij})$  is a  $p$  order polynomial with  $G_p(\tilde{F}_{ij}) = \beta_0 \tilde{F}_{ij} + \beta_1 \tilde{F}_{ij}^2 + \dots + \beta_p \tilde{F}_{ij}^p$ ,  $D_i * G_p(\tilde{F}_{ij})$  that allows different polynomials on the two sides of the discontinuity,  $\gamma_j$  captures firm-level fixed effects and  $\tau$  is the variable of interest.

<sup>14</sup>As a robustness check, we present the analogous figure in Figure 5, but for the starting wages of male workers. As expected, no discontinuity is present. In the same spirit, Figures 6 and 7 test for discontinuities around a different cutoff point, 15 and 25 female workers. As expected, there is no discontinuity in starting female wages around different cutoffs.

<sup>15</sup>Some authors have followed a similar approach (e.e., Lee, 2008b). For a discussion on the methodology and one alternative procedure for inference refer to Lee (2008a).

In principle, the expected discrete change in the provision of child care services mandated by the law encourages the use of RDD to estimate the causal effect of the program on wages. The intuition behind this strategy is that firms that lie just below the threshold and firms that lie just above the threshold are statistically comparable except for the fact that one group of firms is mandated to offer child care service to its female employees and the other group of firms is not. As a result, any discontinuity in the conditional distribution of wages at the threshold could be interpreted as the effect of the law.

The running variable in this case, however, is the maximum number of females working in the firm within a year. In theory, as a result of the optimization problem, firms decide the number of employees and the wage. So, a given firm may reduce its labor cost by not hiring (or firing) the 20th woman, because it is not longer mandated to provide child care services to its female employees. The endogeneity of the running variable creates a threat for identification and, in consequence, a threat for the validity of RDD estimates to reflect the causal effect of the law on wages.

We exploit the availability of longitudinal data to analyze the impact of the law on firm-specific new hires, those leading firms to cross the threshold. One key observation is that large firms tend to cross the threshold at some point. The substitution strategy is not sustainable in the long run for these firms. An evidence of this behavior in our data is that only 24 percent of large and new firms are below the threshold of 20 female workers for the whole period (2005-2013).<sup>16</sup> As a result, the distinction between firms that are below the threshold and those that are above it vanishes in the presence of longitudinal data, reducing the threat to the identification strategy. To justify the identification strategy, we need to formally test for manipulation on the running variable and demonstrate that women hired when the firm is below the threshold are statistically comparable to those hired when the firm is just above the threshold, except for the fact that one group receives employer-paid child care services while the other group does not.

### **Testing for Manipulation in the Running Variable**

A simple graphical test shows the lack of evidence on firms bunching just before reaching the threshold of 20 female workers and the lack of discontinuities in the distribution of firms by the

---

<sup>16</sup>An important fraction of these firms are new firms created in the last two years, which means that the percentage of firms that never cross the threshold would be lower if we control for truncation.

number of female workers. Figure 2 presents the density of firms (new and large) by the number of female workers using both monthly and annual frequency data. In both cases, we observe more mass below than above the cutoff and a tendency but no discontinuity around the cutoff point.

[Figure 2 about here.]

We use a discrete-adjusted version of the test proposed by McCrary (2008) to formally test for potential manipulation of the running variable. This test consists in computing an estimator for the size of discontinuity around the cutoff in the density function of the running variable.

Table 3 presents the estimation of the coefficient associated with a dummy variable indicating whether the firm has 20 or more female workers  $D$ . We estimate a regression of the (log) of the frequency of firms on a low-order polynomial in the number of female workers  $\tilde{F}_{ij}$  and  $D$ . We present estimates for two specifications, one using a polynomial of degree 2 and another using a polynomial of degree 5.<sup>17</sup> We do not compute bandwidths in our parametric approach, but we still need to restrict the regression to the observations that are close to the threshold. For that reason, we present estimates using two different subsamples. The first subsample corresponds to firms with 10 to 30 female workers (Window N\_females=10), and the second to firms with 5 to 35 female workers (Window N\_females=15). In all cases, we present the results with and without additional controls for the average number of workers and the average wage for female and male workers.

We find no evidence of a statistically significant discontinuity in the distribution of firms around the cutoff point. This is true for all the specifications presented. The lack of evidence of bunching is important to justify the validity of our RDD results.<sup>18</sup>

[Table 3 about here.]

## Testing for Discontinuities in Observable Characteristics Around the Cutoff

Our identification strategy compares starting wages of females hired when firms are just below the threshold with the starting wages of females hired right after the firms crosses it. In this context, we need to ensure that women hired when the firm is just below and just above the threshold are

---

<sup>17</sup>We test the fit of the polynomial functional form using a simple goodness of fit test after a graphical analysis of the data. In general, the best fit is attained with polynomials degree 2 and 5, we present the two extreme values but, we prefer the specification with the polynomial with the lowest degree following Gelman and Imbens (2014).

<sup>18</sup>Escobar (2014) finds that manufacturing firms tend to concentrate below the threshold of twenty workers but we finds no evidence of bunching at 19 female workers.

statistically comparable except for the fact that one group receives employer-paid child care services and the other group does not. If this is true, any discontinuity in the conditional distribution of wages at the threshold could be interpreted as the effect of the law. For this purpose, we test for discontinuities in observable characteristics, demographic characteristics, and characteristics of the firm around the threshold.

Figures 3 and 4 present the results of running polynomial regressions on different characteristics of both the individuals and the firms near the cutoff point. The fact that we observe multiple first-time hires in different firms at different times -including the same woman on different dates- help us to ensure the plausibility of the assumptions. The figures evidence that the available covariates (age, marital status, highest completed degree, type of contract and size of the firm) are smooth functions of the assignment variable, conditional on treatment. In consequence, the only reason for the outcome variable to jump at the cutoff is the discontinuity in the level of treatment.

We find that the average age is a decreasing function of the number of female workers in the firm. This should not represent a problem since we are using a local estimation. If we consider that wages increase with age (experience, tenure, etc.), having a relatively older composition of the treatment group would imply that the difference with the control group is even higher than estimated (considering that starting wages increase with age).<sup>19</sup>

[Figure 3 about here.]

[Figure 4 about here.]

Our tests cannot rule out the presence of differences in unobservables such as ability, which in general is associated with higher wages. In that case our estimates would be a lower bound of the total effect.

## 6 Results

Table 4 presents the results of the estimation associated with the regression presented in Equation 4. We test the fit of the polynomial functional form using a simple goodness of fit test after a graphical analysis of the data. In general, the best fit is attained with polynomials of degree

---

<sup>19</sup>Note that RDD does not require these characteristics to be uncorrelated with wages, RDD only requires this characteristics do not have a discontinuous effect on wages (Nichols, 2007).

2, 3 and 4. The results are fairly constant across specifications but as a general rule we prefer specification associated to the polynomial with the lowest degree following Gelman and Imbens (2014).

We present estimates corresponding to two different ranges of data. In the first case, we use females hired for the first time in firms with 10 to 30 female workers. In the second case we use a broader window of 15 female workers around the cutoff point. In all cases, we present the results with and without additional controls for age, age squared, type of contract, schooling, year hired, and region of residence.<sup>20</sup> Although the results are not very different, it is useful to evaluate the impact of controlling for other variables that affect starting wages.

In principle, if the identification strategy is valid, covariates should be redundant. According to Imbens and Lemieux (2008), however, including covariates may be useful to eliminate small sample biases present in the basic specification, and improve the precision. In addition, they can be useful for evaluating the plausibility of the identification strategy.

On the other hand, Nichols (2007) considers that including covariates is generally a very bad idea. Although the covariates may improve efficiency by reducing residual variance, they could also reduce efficiency due to estimation error in their coefficients. In addition, any violations of the assumptions that such covariates are exogenous and have a linear impact on mean treatment and outcomes could greatly increase bias. The estimate of the effect slightly decreases in magnitude and is less precise after controlling for covariates.

[Table 4 about here.]

Our results indicate that women hired in large firms of 20 or more female workers with mandatory employer-paid child care services are penalized with lower starting wages compared with the wages of women hired in firms with no such requirements. The size of the difference ranges between CLP\$24,000 to CLP\$53,000 (US\$39-US\$87) depending on the specification.<sup>21</sup>

The appendix presents the results of our estimation using different sizes of firms to confirm that only large firms adjust starting wages in reaction to the policy. More precisely, in firms with 20-50 workers (small to medium according to the traditional categories used in the country) we do not

---

<sup>20</sup>There is no consensus on the convenience of controlling for other variables.

<sup>21</sup>Values expressed in Chilean pesos of 2009. Values in dollars computed using the exchange rate in effect on April 2015 of 609.89 Chilean pesos per US dollar.

find any statistically significant difference in starting wages of females. (see Tables 5 and 6). The estimated effects increase when we restrict the sample to firms with 100 or more workers, but the magnitude is smaller compared to our results for large firms -following the traditional definition of 200 or more workers- (see Table 7).

As a robustness check, we also present results for firms with 250 or more workers (see Table 8). These results are in line with the observation that only large firms comply with the law and in consequence adjust starting wages accordingly. It is also consistent with the observation that larger firms are subject to stringent vigilance and control procedures.

The most conservative way of interpreting the results is as a lower bound of the total effect of the legislation on the wages of females working at large firms. The imperfect compliance with the law is likely to be associated with an underestimation of the difference in wages between women working at firms with mandatory employer-paid child care services and women working at firms without this requirement. We assume that all large firms that employ 20 or more workers are paying for child care services when, in fact, 10 percent of firms do not comply with the law. Women hired in noncompliant firms should not experience any effect on their wage. If we were able to remove those observations, the average wage of female workers above the threshold will be even lower, which implies a larger difference with the wage of females below the threshold.

Considering the reported average per capita monthly cost of providing child care services (CLP\$75.000 -CLP\$100.000) the results at first sight may suggest a low degree of pass-through.<sup>22</sup> Nevertheless, to analyze the results in perspective, it is important to consider that the cost of child care provision is only paid to the women with young children, while the wages include all registered female workers. In addition, the present estimates only consider starting wages. Given the importance of initial conditions on future wages, the effect of the policy must be analyzed not only in terms of the magnitude in a given period, but also in terms of the long-run consequences implied. In particular, a low starting wage is highly correlated with lower future wages.

---

<sup>22</sup>The cost of child care service provision from (Dirección del Trabajo, 2008). Values are expressed in Chilean pesos of 2008.

## 7 Conclusions

The present document quantifies the impact of mandated provision of child care services in Chile finding sizable effects on the starting wages of female employees. This is not surprising, given that mandated benefits can be interpreted as a tax. As Summers (1989) points out, the tax rate is equal to the difference between the employer's cost of providing the benefit and the employee's valuation. Since it is difficult to compute precisely the employee's valuation, we estimate the extent to which the cost of mandatory legislation translates into lower wages -specifically, lower starting wages.

Our results indicate that women hired in firms with mandatory employer-paid child care services are penalized with lower starting wages compared with the wages of their counterparts hired with no such requirements. As presented in Table 3, the size of the difference in large firms created after 2005 ranges between CLP\$24,000 to CLP\$53,000 (US\$39-US\$87) depending on the specification.<sup>23</sup> These numbers represent between 9 and 20 percent of the average starting wage of women hired in firms below the threshold of 20 female workers.

As a caution note, it is important to clarify that this paper concentrates on one margin of the adjustment: starting wages of female workers. We estimate the size of the adjustment for large firms when they decide to cross the threshold of 20 female workers. In consequence, our results may not be interpreted as evidence for the lack of adjustment through substitution of workers by gender. The law may have an important impact on the hiring patterns of other firms that never cross the threshold (e.g., medium-sized firms). This analysis is more difficult to perform rigorously, however, considering the low compliance with the law by those firms.

This paper highlights the adverse unintended effects of a law for the group that is intended to benefit from it. The objective of the law is to guarantee the right of working mothers to have child care services and to promote the child-mother close relationship and healthy development of the children, as well as reduce gender disparities in the labor market. The law creates a distortion, however, affecting differentially the cost of hiring women. This creates a wage disadvantage for women, lower incentives to participate, and higher gender disparities. Finally, considering the importance of starting wages on future wages, computing the long-run effects of the lower starting wages for women may be an interesting extension of the present paper.

### Robustness Checks

#### Graphical Discontinuity Test: Different Cutoffs and Different Populations

As a robustness check, we present check the presence of any discontinuities in the starting wages of male workers. As expected, no discontinuity is present. In the same spirit, we test for discontinuities around a different cutoff point, 15 and 25 female workers. As expected, there is no discontinuity in starting female wages around different cutoffs.

[Figure 5 about here.]

[Figure 6 about here.]

Table 1: Descriptive Statistics: Firms by Size and Time of Creation (2005-2013)

	<b>All firms</b>	<b>Large</b>	<b>New</b>	<b>New and large</b>
N_firms	837,899	7,190	525,181	1,912
Crossing	22,033	5,397	7,419	1,224
	2.6%	75.1%	1.4%	64%
N_times crossing	2.82	3.00	2.20	2.41
Observations (month-year)	30,451,078	704,903	13,392,272	109,434

Note: Firms are classified as large if they employ 200 or more workers in a calendar year. Crossing refers to the number of firms that cross the threshold of 20 female workers at least once. N\_times crossing refers to the average number of times firms cross the threshold.

Table 2: Descriptive Statistics: Characteristics of Firms where Female Workers were Hired for the First Time and Starting Wage

<b>Variable</b>	<b>Mean</b>	<b>Std. Dev.</b>	<b>Min</b>	<b>Max</b>
N_workers	2,059.023	3,248.03	200	20,620
N_female workers	927.6	1,733.77	1	12,101
N_male workers	653.96	1,245.55	0	8,572
Starting wage	174,975	152,566.9	21,063.31	1,253,090
Average wage females firm	212,256.8	163,370.9	0	2,015,287
Average wage males firm	247,426.1	187,017.5	0	2,030,768
Above	0.96	0.19	0	1
Obs (hires)	1'397,823			
N firms	1,912			

Note: "N\_workers" is the average of the number of workers employed in the firm hiring new female workers over the period 2005-2013, "N\_female workers" is the average number of female workers employed in the firm where the individual was hired; the analogous is true for "N\_male workers", "Starting wage" for female and male workers is the average of the real starting wage in Chilean pesos of 2009 for the females and males in the sample, "Average wage females/males firm" corresponds to the average wage of female or male workers working at the firm where the female was hired, "above" is a dummy variable for the firms with 20 or more female workers: the number of observations corresponds to individual hires and "N firms" is the number of firms considered.

Table 3: Adapted McCrary Test for Discrete Running Variable

Window N_females	10	15
Poly. degree 2	-0.08	-0.03
Poly. degree 2 covar	0.04	-0.03
Poly. degree 5	-0.15	0.10
Poly. degree 5 covar	-0.27	0.11

\*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

Notes: The table presents the results of the estimation for the size of discontinuity around the cutoff in the density function of the running variable. “Poly. degree 2” and “Poly. degree 5” refer to the results corresponding to the use of polynomials of degree 2 and 5, respectively. In both cases, we present the results with and without additional controls for the average number of workers and the average wage for female and male workers; “covar” refers to the estimations with additional covariates. “Window Nfemales” refers to the subsample of firms used in the estimation we use a window of 10 and 15 female workers around the threshold of 20, we used clustered-consistent standard errors (clustering on individual values of the number of female workers centered around zero,  $\tilde{F}_{ij}$ ).

Table 4: Main Results: Female Starting Wages at New and Large Firms

Polynomial order		10-30 female workers		5-35 female workers	
2	Baseline	-28,781.9	***	-29,042	**
2	Covariates	-26,310.4	***	-24,433	*
3	Baseline	-26,121.9	*	-16,266	
3	Covariates	-23,694.1		-13,174	
4	Baseline	-33,657.3		-11,051	
4	Covariates	-52,772.0	*	-3,837	

\*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

Notes: The table presents the results of the estimation associated with the regression presented in Equation 4. We present the results associated polynomials of degree 2, 3 and 4, which are the regressions that best fitted the data. The first column presents results in the subsample of females hired for the first time in firms with 10-30 female workers, while the second column includes a wider range of 15 female workers around the discontinuity point. In all cases, we present the results for the baseline case (with no covariates) and for the case that controls for covariates (age, age squared, type of contract, schooling, year and region of residence). We used clustered-consistent standard errors (clustering at the firm level).

Table 5: Main Results: Female Starting Wages New Firms with More than 20 Workers

Polynomial order		10-30 female workers		5-35 female workers
2	Baseline	-940.67		1899.8

## FOREWORD

Under President Enrique Peña Nieto's leadership, Mexico has put together the most ambitious reform package of any OECD country in recent times, forged the political consensus necessary to approve it through the unprecedented *Pacto por México*, promoted these and other reforms in Congress and has started implementing them. The battery of reforms has addressed challenges in policy areas that had been waiting for deep changes for decades, including education, labour, tax, health, telecommunication, and energy and justice, among many others.

It is still early to fully assess the impact of these changes, but some are already starting to bear fruit. The education reform has led to the first evaluations of teachers and a new education model based on global competencies. Labour, tax and social security reforms have helped reduce informality, with more than 3 million formal jobs created since 2012. Thanks to reforms to the health care sector, insurers are co-operating more and households' out-of-pocket spending has fallen. Public awareness campaigns and the introduction of a sugar tax have led to a slowing in the growth of obesity. Reforms to the telecommunication sector have boosted competition. The number of mobile broadband subscriptions more than tripled between 2012 and 2016, while prices declined by up to 75%. The energy reform opened Mexico's energy sector to private investment and competition, securing private investments of almost USD 80 billion. Changes to constitutional rights, the criminal justice system and everyday justice are helping to better meet the needs of citizens and firms.

The OECD has accompanied and supported the Mexican government in the design, development and implementation of many of these reforms. Since 2013, more than 40 publications on Mexico have been launched, analysing the country's challenges and proposing policies to address them. In many cases, these analyses were complemented by hands-on support to implement legislative and institutional changes and make reform happen. This was not only to the benefit of Mexico, but also to the OECD. Through this constant interaction the OECD learned a great deal and improved its capacity to support countries in their reform efforts.

Mexico still faces important challenges. At close to 17%, Mexico's poverty rate is almost twice the OECD average and regional inequalities remain substantial. Productivity growth is low in many sectors and around 30 million people continue to work in informal jobs without access to stable incomes, training opportunities, financial services, health care or pension coverage. And while the share of low-performing students has fallen, Mexico's 15-year-old students still score below the OECD average measured by the OECD's Programme for International Student Assessment. Enforcement of the rule of law remains weak, especially at state and municipal levels, contributing to high levels of crime and insecurity. Mexico has the highest homicide rate in the OECD and only 46% of people feel safe walking alone at night, well below the OECD average of 68%. Corruption is still an important issue, with more than 60% of people believing that government corruption is widespread.

This is why it is crucial for Mexico to continue its reform agenda. It is imperative to strengthen some of the recent reforms, and to keep updating and promoting them to ensure their effective implementation. The OECD stands ready to further accompany Mexico on this path. Together, let us continue to design, promote and implement better policies for better lives in Mexico and worldwide.

Angel Gurría  
OECD Secretary-General

## INTRODUCTION

### MEXICO HAS BEEN A REFORM FRONTRUNNER

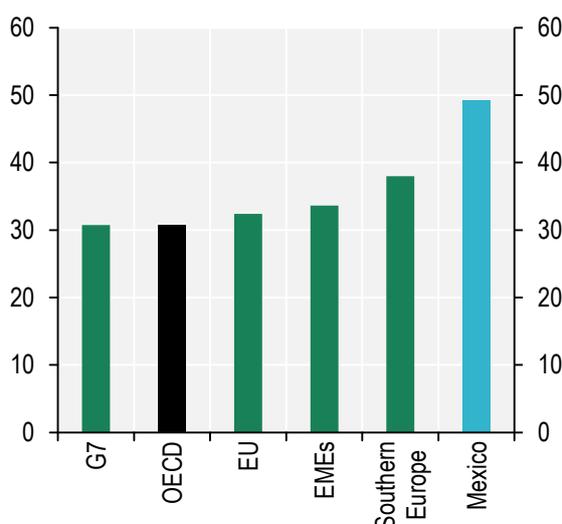

Structural reforms introduced during the administration of President Enrique Peña Nieto have been bold and comprehensive. Over the period 2013-16, Mexico showed one of the highest reform activities among OECD countries (Figure 1.1, panel A). Reform action was triggered by the *Pacto por México*, a historic agreement between the country's three major political parties to put the country back on a path of prosperity after three decades of low growth. Key laws and constitutional amendments were approved. Secondary laws or regulations were passed involving changes in product and labour market regulation and competition policy, as well as measures to improve the efficiency of the tax system. The *Pacto por México* was complemented by reforms aimed at improving the quality of the education and health care systems, enhancing the efficiency of the judiciary system, liberalising the financial sector, strengthening innovation, reducing informality and boosting women's labour market participation.

Mexico's ambitious structural reforms and sound macroeconomic policies have ensured the resilience of the highly open Mexican economy in the face of difficult global conditions. Productivity growth has picked up in sectors that have benefitted from reforms, notably energy, finance, and telecommunication. The OECD estimated that a subset of Mexico's reforms could add 2 percentage points to GDP growth after five years (Figure 1.1, panel B). Yet other sectors lag behind, suffering from overly stringent local regulations, weak legal institutions, corruption and insufficient financial development. Productivity growth is also constrained by longstanding social problems, in particular the poor skills level of the workforce and high rate of informality, which traps workers in precarious jobs.

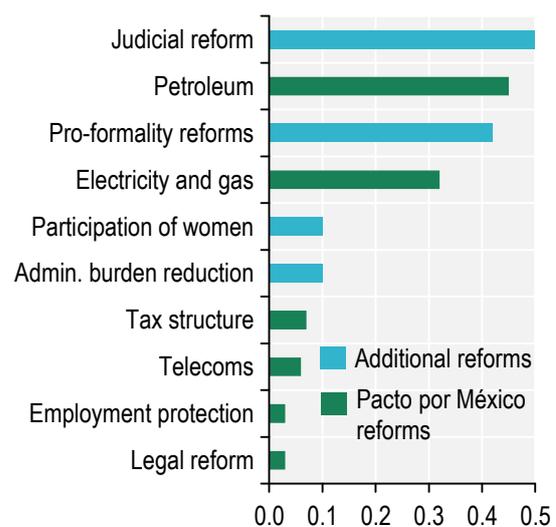

Mexico's reform intensity over the recent past has been impressive. Each of the reforms has been wide-ranging in scope and is intended to address the main challenges in its respective sector. The OECD was strongly committed to Mexico's reform agenda and supported it in many ways.

**Figure 1.1. Mexico's high reform activity is contributing to better economic performance**

A. Share of OECD *Going for Growth* recommendations with significant action taken, 2013-16, in %

B. Expected boost to annual growth on average over the 5 years following reform, in %

Note: Panel A: EU includes OECD member countries that are also part of the EU. EMEs include Brazil, Chile, China, Colombia, Hungary, India, Indonesia, Mexico, Poland, South Africa and Turkey. Southern Europe includes Greece, Italy, Portugal and Spain.

## INTRODUCTION

### PROGRESS NEEDS TO BE MORE INCLUSIVE TO IMPROVE THE WELL-BEING OF ALL

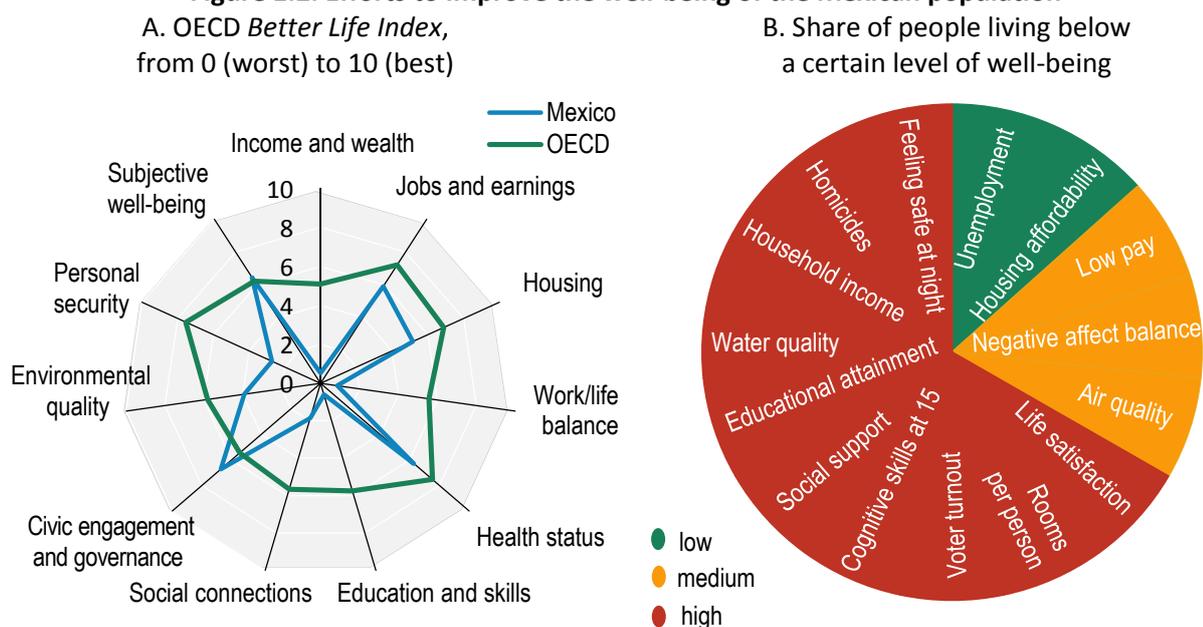

Reforms launched over the past five years have laid the foundation for higher prosperity and well-being. Fully implementing these legislative and institutional changes is now crucial. Equipping Mexicans with relevant skills and improving access to good-quality jobs will allow them to fully benefit from productivity-enhancing reforms.

Helped by the reforms, well-being has improved over the last five years. The share of informal workers fell by 3 percentage points, giving more workers, particularly the most vulnerable, access to stable incomes, training opportunities, financial services, health care and pension coverage. Health care and education coverage have improved, as have education outcomes, including for low-performing students.

But inequalities persist, driven by the divergence of a highly productive modern economy in the North and Centre and a lower-productivity traditional economy with small-scale informal firms in the South. Income remains highly concentrated: the richest 20% earn ten times more than the poorest 20%, compared to 5.4 times in the OECD (Figure 1.2, panel A). Despite a fall in extreme poverty, many families remain poor, and the potential for children to do better than their parents lags behind other OECD countries. Mexico has a high share of people suffering from deprivation in many aspects of well-being including skills, social support and security (Figure 1.2, panel B). Regional disparities remain substantial. Living in one of the worst-faring states can mean being four times as likely to be at risk of poverty, seven times as likely to abandon school and seven times as likely to work longer hours for lower pay than people living in the best-faring states.

The structural reforms launched under President Peña Nieto were an important step towards a stronger, greener and more inclusive Mexico. Yet a lot of work still lies ahead. Most importantly, legislative and institutional changes now need to be fully implemented, including at the local level. The limited administrative capacity of many state and local governments calls for strong support and monitoring at the national level. Effective reform implementation also requires continued efforts to address institutional bottlenecks, including with respect to the rule of law and corruption. Moreover, for people to fully contribute to higher economic growth, equipping them with good and relevant skills as well as good health is crucial.

## FOSTERING THE WELL-BEING OF MEXICAN PEOPLE

### REFORMS HAVE HELPED REDUCE POVERTY, THOUGH IT REMAINS HIGH

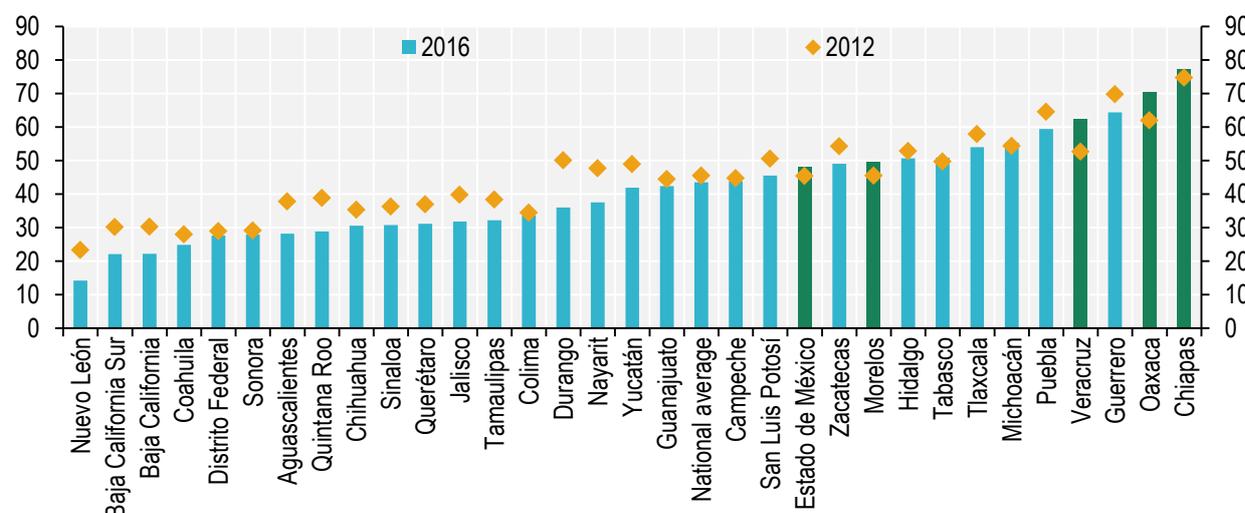

Mexico's 2013-18 National Development Plan significantly increased social spending and improved the targeting of government transfers. The conditional cash transfer programme *Prospera* is now better linked to educational services, vocational training, formal employment opportunities and formal banking, promoting the self-sufficiency of beneficiaries. The minimum age of the social pension was lowered to include those aged 65 and above. While this guarantees a minimum income level, the benefit level is still below the extreme poverty line.

Helped by these reforms and Mexico's National Inclusion Strategy, the share of people living on less than 50% of the median income fell by 2 percentage points during 2012-14. The poverty rate is still almost twice the OECD average, however, with children and the elderly most affected. Poverty rates differ markedly across states. The share of people living on less than 50% of median income ranges from 6.8% in Nuevo León to 50% in Chiapas. A broader measure of poverty that considers non-income dimensions of well-being confirms these regional differences (Figure 2.1). While multidimensional poverty decreased in 25 out of 31 Mexican states and Mexico City between 2012 and 2016, it increased further in states that already had the highest prevalence of poverty. To address regional disparities, the Federal Law on Special Economic Zones was passed in 2016 to foster economic development in Mexico's poorest states. Mexico is one of the few OECD countries to have experienced a decline in income inequality during the 1990s until the mid-2000s, although the level of inequality has since stagnated and remains one of the highest in the OECD.

To further reduce poverty and inequality, social programmes and financing must be strengthened, consolidating recent achievements. Policy strategies must be comprehensive and targeted at specific states. A common database on a single technological platform may help improve co-ordination between levels of government and enhance the targeting of social programmes. In addition, efforts must ensure the equal participation of disadvantaged groups, including indigenous people.

Working with SEDESOL, the OECD is supporting Mexico in assessing progress over the past 25 years along the various dimensions of poverty and identifying areas where further progress is needed.

**Figure 2.1. Poverty has fallen in most Mexican states**  
Poverty rate in %, measured along eight dimensions of well-being

Note: States with a fall (rise) in poverty are marked in blue (green). The eight well-being dimensions are household income, education, housing quality, social cohesion, access to health services, security, housing services and food. For details, see <http://www.coneval.org.mx/SalaPrensa/Comunicadosprensa/Documents/Comunicado-09-medicion-pobreza-2016.pdf>.

## FOSTERING THE WELL-BEING OF MEXICAN PEOPLE

### MEXICO HAS MANAGED TO REDUCE THE SHARE OF LOW PERFORMERS IN ITS EDUCATION SYSTEM

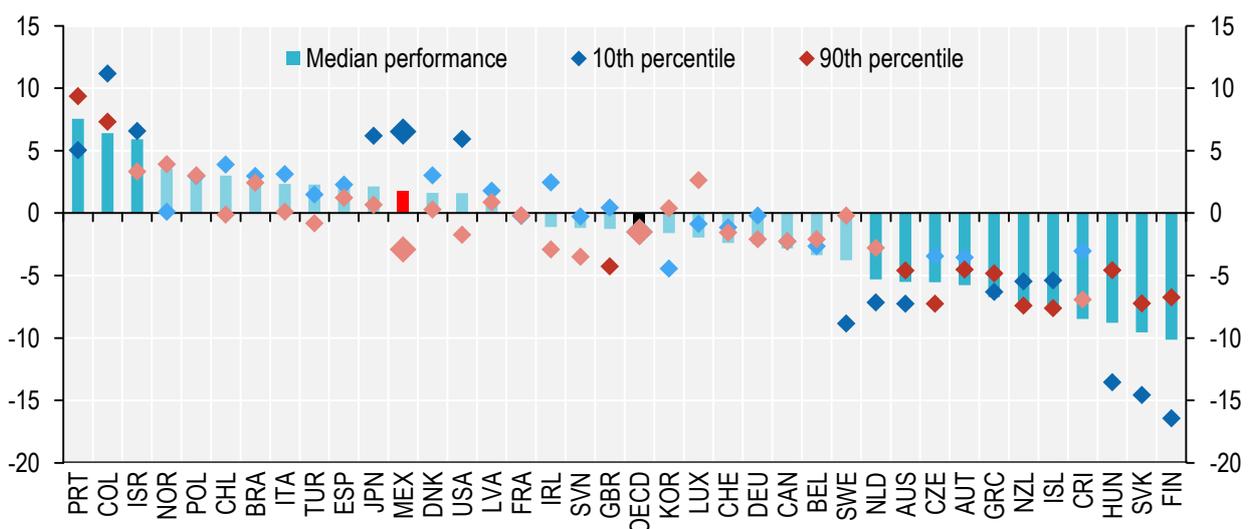

Mexico's education reform is well-aligned with previous OECD policy recommendations. They include putting students and schools at the centre of the education system, implementing a new curriculum and raising the quality of the teaching profession.

Mexico has made significant progress in improving the coverage and quality of its education system. Today, nearly all children between the ages of 4 and 14 are in school. President Peña Nieto's ground-breaking constitutional reform improved the education system by advancing an agenda with a common basic goal: putting students and schools at the centre of the system to improve learning outcomes. Mexico has been working towards this goal by improving school environments, investing in more and better infrastructure, refining evaluation and assessment practices, fostering equity and inclusion, and raising the quality of the teaching profession. Mexico's new education model was introduced in 2017 with the aim of ensuring that children receive a quality education that prepares them for 21<sup>st</sup>-century challenges.

While some 48% of students in Mexico are low performers in science (meaning they did not achieve Level 2 in the OECD's Programme for International Student Assessment [PISA]), this group showed an average improvement of 7 score points every three years between 2006 and 2015 (Figure 2.2). It is noteworthy that Mexico was able to make this progress while increasing access to education: the total population of 15-year-olds enrolled in grade 7 or above since 2003 has increased by 300 000, of which 60 000 have been added just since 2012.

Mexico should continue improving access to education, reducing its share of low-performing students and working to raise the number of high-performing students, as this also remains behind the OECD average. Mexico's 15-year-old students still consistently score below the OECD average across all domains measured by PISA. Large performance and completion gaps persist, especially for students with indigenous and low socio-economic backgrounds.

**Figure 2.2. Mexico has seen improvements among its lowest performers**  
Average three-year trends in PISA scores in science

Note: Statistically significant differences are marked in a darker tone. The average three-year trend is the average rate of change per three-year period between the earliest available measurement in PISA and PISA 2015. For countries and economies with more than one available measurement, the average three-year trend is calculated with a linear regression model.

## FOSTERING THE WELL-BEING OF MEXICAN PEOPLE

### EDUCATION AND TRAINING HAVE BECOME MORE RELEVANT TO THE WORLD OF WORK

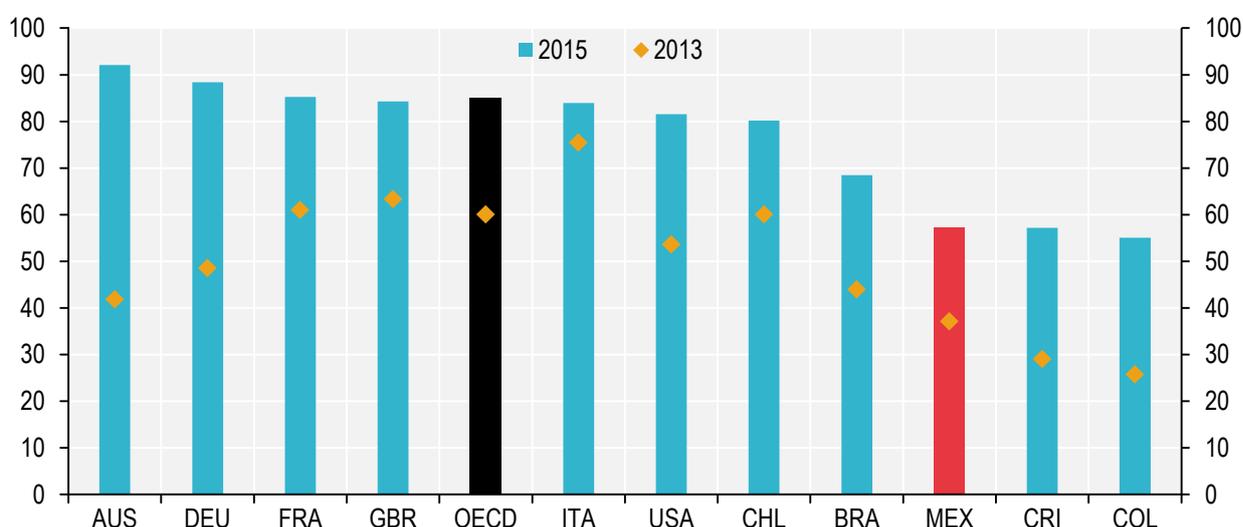

While Mexico has made progress at the educational level, young people also need the right mix of skills to keep abreast of changing labour market needs and succeed in adult life. To raise the skills of its youth population, Mexico made upper secondary education compulsory in 2012 with the goal of attaining universal coverage by 2021. Enrolment rates in upper secondary and tertiary education have seen impressive increases, but this progress has not been equitable. The share of Mexican adults with upper secondary and tertiary education remains below the OECD average (Figure 2.3). Moreover, upper-secondary drop-out rates are very high. This leaves the country with a comparatively low-skilled workforce.

Raising educational attainment alone will not be enough. Skills must also be relevant to the needs of the labour market. To improve the labour market relevance of its education and training system, Mexico has expanded private sector involvement, increased the number of apprenticeships, and raised the supply of training and vocational programmes. The labour reform enhanced the certification of skills and led to the creation of commissions to promote training. Mexico has also been encouraging young people to pursue careers and research in science, technology, engineering, and mathematics (STEM) fields, in line with labour market developments. In 2016, one quarter of adults with tertiary education had a degree in one of these fields, on par with the OECD average.

Closing the gap between the supply and demand of skills requires co-ordinated efforts among different ministries and various stakeholders. In particular, strong commitment by businesses to invest in their workers is needed. The National Productivity Committee (NPC) was created to help facilitate this co-ordination by aligning skills policies with industry needs. The NPC's mandate includes co-operation with subnational authorities. In addition, tackling skills imbalances requires up-to-date and high-quality information on skills needs to guide training provision and career choices.

The OECD Skills Strategy project provided an extensive diagnosis and 11 specific recommendations as inputs to Mexico's long-term skills development strategy.

**Figure 2.3. Participation in upper secondary education is rising, but is still below the OECD average**  
Enrolment rates of 15-19 year-olds, 2015

Source: OECD, *Education at a Glance 2017 Database*, <http://stats.oecd.org>.

## FOSTERING THE WELL-BEING OF MEXICAN PEOPLE

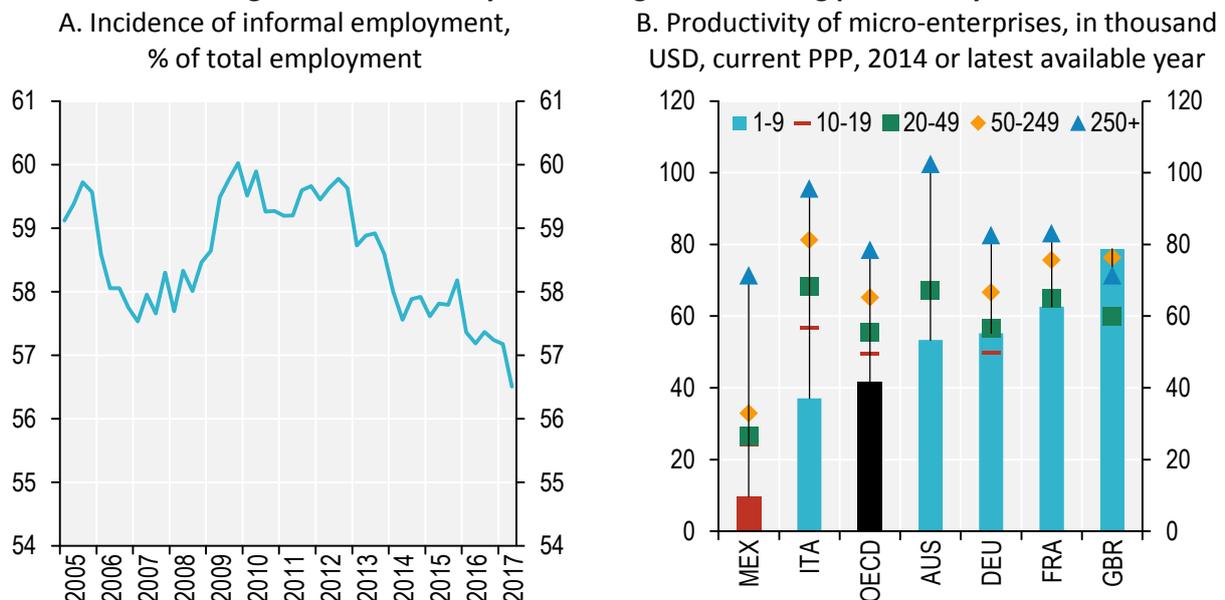

The OECD supported Mexico in its endeavour to address informality through various editions of its *Economic Surveys on Mexico*, published every two years. The 2011 edition included a special chapter on informality. Moreover, the topic was also discussed in the 2013 *Getting it Right* report.

### INFORMAL EMPLOYMENT IN MEXICO IS DECREASING

While informality remains high, Mexico has made progress over the past five years, reducing the proportion of informal workers from 59.6% in the last quarter of 2012 to 56.5% by the end of the first half of 2017 (Figure 2.4, panel A). Over 3 million formal jobs were created, with almost a quarter of them going to young people. Informality is concentrated in very small informal firms (which employ more than half of Mexico's informal workers) and in the South. It is associated with low productivity, as resources remain trapped in informal activities and are not used in more productive ones (Figure 2.4, panel B). Furthermore, workers in informal firms tend to receive less training and are less likely to accumulate human capital. They also suffer from lower job quality along several dimensions, including pay, labour market security and quality of the working environment.

The decline in informality was helped by a number of reforms. The government stepped up supervision for firms with 50 or fewer employees. It introduced labour, tax and social security reforms, simplifying tax compliance and substantially reducing personal, social security, value added and excise tax obligations for the first decade of firms' operation. These reforms, which include incentives to help new firms expand (including access to government-backed financing and training and a series of electronic tools to simplify tax compliance), have induced 1.5 million informal firms to join the tax system since 2014. There are still many efforts to be taken to help achieve the goals of these reforms, for instance by increasing awareness and information about how to make the best out of the social security regime for incorporation. Going forward, Mexico could also consider extending and further enhancing regulation and supervision to reduce state-level informality.

**Figure 2.4. Informality remains high, constraining productivity**

Note: Panel A: The informality rate is the percentage of employed people not covered by social security or working in unregistered economic units. Panel B: Value added per person employed. MEX data refer to establishments.

## FOSTERING THE WELL-BEING OF MEXICAN PEOPLE

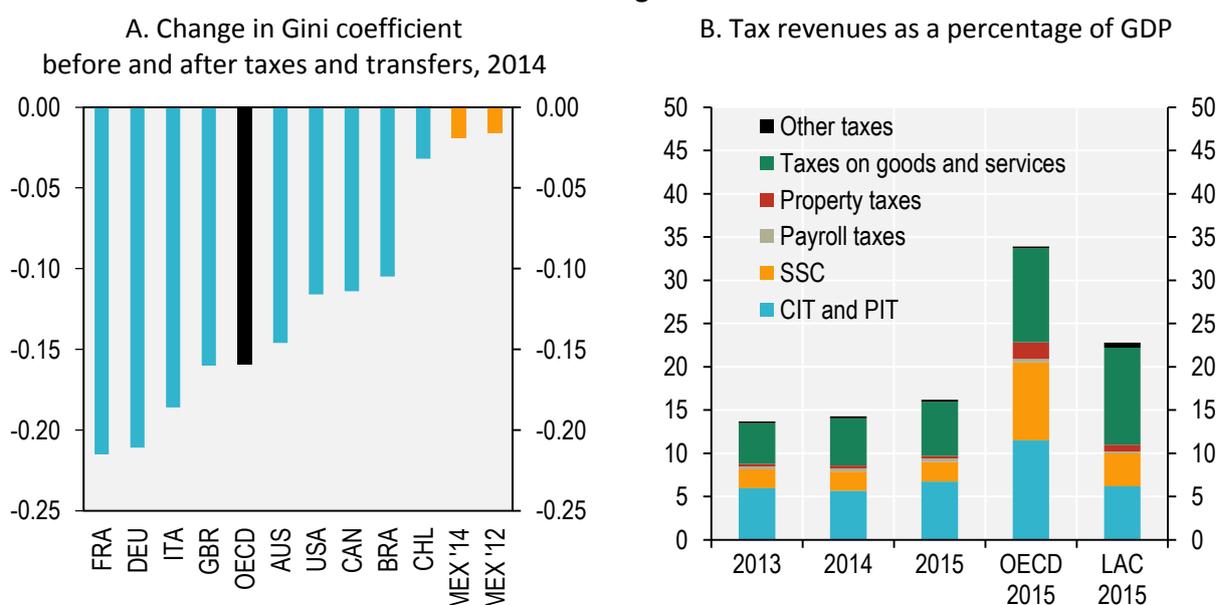

### TAX REFORM HAS CONTRIBUTED TO BETTER EQUALITY

In October 2013, Mexico introduced an ambitious tax reform which took effect the following year. Many of the changes were aligned with OECD tax policy recommendations. The top personal income tax rate was raised to 35%, and limits were imposed on tax deductions. A capital gains and dividend tax of 10% was also introduced. In terms of corporate taxation, limits on depreciation allowances were imposed and an alternative tax regime was eliminated. A number of loopholes and exemptions that allowed for accelerated deduction of investment expenses were removed or reformed. The preferential tax treatment of *maquiladoras* was revised to make it more neutral. Consumption taxation was broadened by abolishing reduced VAT rates in the border regions, and special exemptions for *maquiladoras* were removed. Mexico also introduced a tax on high-caloric foods and sweetened beverages.

The tax reform helped increase the redistributive effect of the tax and transfer system (Figure 2.5, panel A). Before the reform, Mexico's tax and transfer system was least effective among OECD countries in reducing income inequality. Even after the reform, income inequality remains above the OECD average, suggesting that further reforms will be needed. The tax reform also contributed to higher tax revenues. Total tax revenues increased by more than 2.5 percentage points between 2013 and 2015 (Figure 2.5, panel B), with taxes on goods and services (+ about 1.5 percentage points) and corporate and personal income taxes (+ about 0.8 percentage points) recording the largest increases. Nevertheless, tax revenues remain low when compared to OECD countries and other countries from Latin America and the Caribbean.

The OECD provided the Mexican government with various assessments of the strengths and weaknesses of the country's tax system. The OECD also contributed with tax-related technical advice.

**Figure 2.5. The 2013 tax reform has made the tax system slightly more redistributive and contributed to higher tax revenues**

Note: In panel B, SSC denotes social security contributions, CIT corporate income taxes and PIT personal income taxes. The numbers do not include oil royalties, which are classified as non-tax revenues and amounted to 4.6% of GDP in Mexico in 2015.

## FOSTERING THE WELL-BEING OF MEXICAN PEOPLE

### MEXICO MUST KEEP WORKING TO REACH GENDER EQUALITY

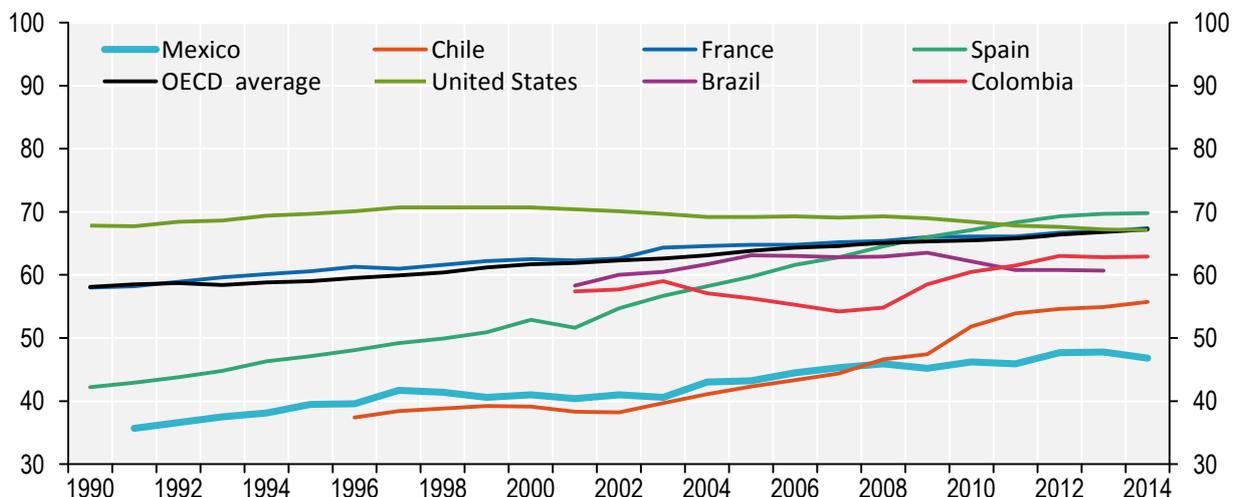

To help Mexico promote gender equality and the empowerment of women in economic and public life, the OECD prepared the 2017 review *Building an Inclusive Mexico: Policies and Good Governance for Gender Equality in collaboration with the National Women's Institute (INMUJERES)*.

In recent years Mexico has enacted good policies to close gender gaps in labour market outcomes. Gender equality budgets are being increased, with major resources dedicated to advancing women's economic autonomy. In the framework of the new educational model, public scholarships are keeping more girls in upper secondary school, and the Ministry of Education has made it a priority to inspire girls and young women to study science, technology, engineering, and mathematics (STEM) fields, as evidenced by the *NiñaSTEM Pueden* initiative. The increase in the quantity and quality of childcare centres, such as the Ministry of Social Development's *Estancias Infantiles*, are giving mothers more childcare options – a key tool for improving women's labour force participation. Programme changes to *Prospera* are helping to better link recipient mothers to the labour market. In 2017, financial sector regulation was changed to enhance women's participation in boards and decision-making positions in companies listed on the Mexican Stock Exchange. Moreover, women's access to financial services was improved by strengthening the National Development Banking programmes, especially for women living in poverty and in vulnerable conditions.

While these are steps in the right direction, Mexico still has a long way to go on the road to gender equality. At 16.5%, the gender gap in earnings for full-time employees was still substantial in 2016. Women make up a majority of all graduates with bachelor degrees (54%), and a very slight minority of doctoral graduates (48%). Although the labour force participation of women keeps rising (Figure 2.6), Mexico continues to have the second-largest gender employment gap in the OECD. Among women who work, more than half hold informal jobs and women perform over 75% of all unpaid housework and childcare. Mothers, in particular, have a difficult time engaging in paid work due to insufficient good-quality and affordable childcare options (even if availability has improved in recent years). Violence against women is also a major problem. In 2016, 34% of women aged over 15 years had experienced physical violence at least once in their lifetime according to Mexico's National Institute of Statistics and Geography, and 41% of women over 15 years had experienced sexual violence at least once in their lifetime.

**Figure 2.6. Mexican women's labour force participation rate is improving, but still lags behind most of the OECD**

Labour force participation rates for women aged 15 to 64

Source: OECD (2017), *Building an Inclusive Mexico: Policies and Good Governance for Gender Equality*, <http://dx.doi.org/10.1787/9789264265493-en>.

### WOMEN'S PARTICIPATION IN PUBLIC BODIES IS RISING

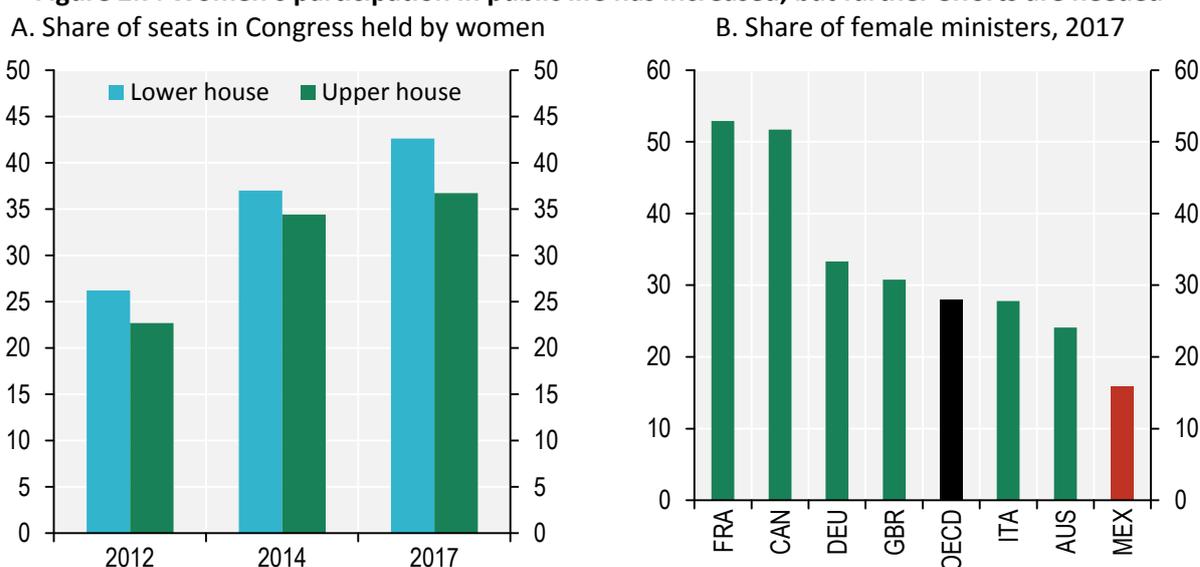

Since 2013, important reforms have been initiated – notably by the Presidency and INMUJERES – to advance gender equality in public institutions. Major steps include the incorporation of a gender perspective in the National Development Plan 2013-18, the 2013-18 National Programme for Equal Opportunities and Non-Discrimination against Women, and a 2014 electoral reform introducing gender parity. Thanks to these reforms, Mexico has made significant progress in increasing women's representation in Congress (Figure 2.7, panel A), placing itself among the top OECD countries in terms of women's representation in the national legislature. Women made up 42.6% of seats in Mexico's Chamber of Deputies in 2017, up from 26.2% in 2012 (Figure 2.7, panel A) and well above the OECD average of 28.8%.

But Mexico still falls short of meeting its constitutional commitment to parity. Only 16 of 56 ordinary commissions in the Chamber of Deputies were presided over by women in 2016. Women still hold far fewer political decision-making positions in the executive branch than their male counterparts. At the federal level, only three of 19 (15.8%) ministerial positions were held by women in 2017, lower than in 2012 (21.1%) and lower than the OECD average (27.9%; Figure 2.7, panel B). While Mexican women are well represented in the Mexican Federal Public Administration (accounting for 51% of public employees in 2016), they fill only one-third of managerial positions. The same applies to the judiciary branch, where women occupied only 2 out of 11 seats in the Supreme Court in 2015.

To tackle the barriers faced by women in public decision-making positions, including political harassment and violence against women, sexual harassment and difficulties in balancing professional and personal life, Mexico created the Mexican Standard on Labour Equality and Non-Discrimination. This certifies public and private workplaces, including with respect to women's representation in decision-making. Mexico needs to continue embedding gender equality considerations in all government actions, including policies, budgets, services and internal working processes.

The OECD supported Mexico's quest for greater gender equality through the 2015 OECD Recommendation on Gender Equality in Public Life and the 2013 OECD Recommendation on Gender Equality in Education, Employment and Entrepreneurship.

**Figure 2.7. Women's participation in public life has increased, but further efforts are needed**

## FOSTERING THE WELL-BEING OF MEXICAN PEOPLE

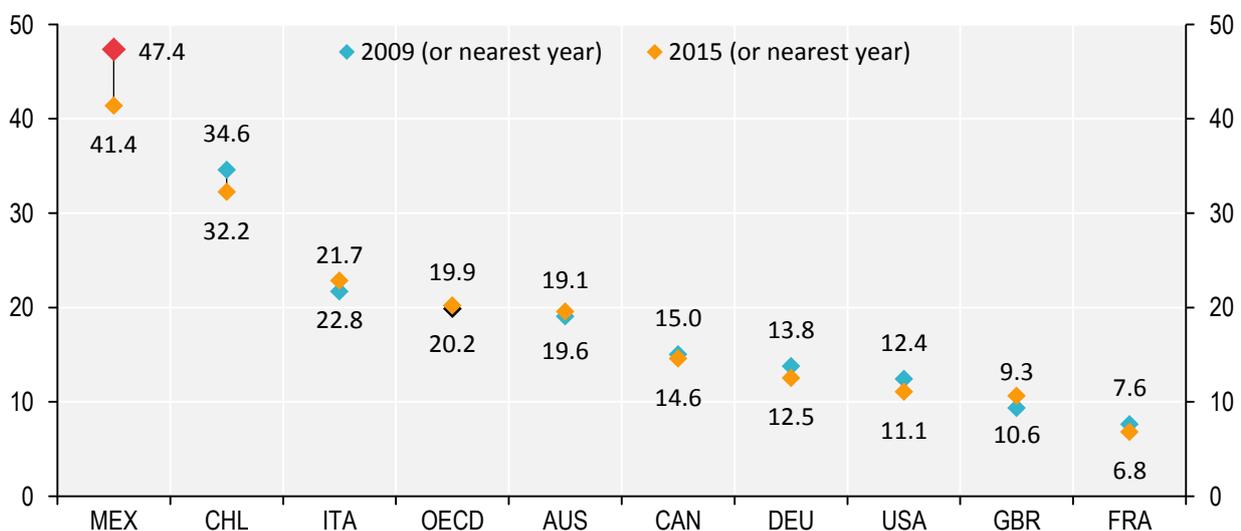

### MEXICO IS ADVANCING TOWARDS A HIGH-PERFORMING HEALTH SYSTEM

The OECD's 2016 *Health System Review of Mexico* identified steps that Mexico can take in the short and medium term to build a more equitable, efficient and sustainable health system.

Mexico has made progress in creating a healthier society and building a more efficient and equitable health system. Public health campaigns have been very successful. The growth in obesity is slowing, and the share of heavy drinkers and smokers is substantially lower than in most other OECD countries. A campaign to vaccinate against influenza reached 82% of Mexicans aged over 65, far exceeding the OECD average of 43%. A fundamental challenge is that Mexican health care is provided through a cluster of disconnected subsystems. Efforts to restructure the public health system around patients' needs are slowly bearing fruit. Health care insurers are co-operating more, developing shared standards and indicators of the quality of care. More service-exchange agreements among public institutions are being signed, allowing patients from one insurer to use the clinics of another. In 2016, the National Agreement towards the Universalisation of Health Care Services was adopted, seeking universal coverage, exchange of services and joint planning of infrastructure among public health care service providers. Most importantly, out-of-pocket spending is falling, meaning that insurance is improving (Figure 2.8).

Much remains to be done, however. Health outcomes in Mexico are, in general, worse than in other OECD countries. The gap in life expectancy between Mexico (75.0 years at birth) and other OECD countries (80.6 years on average) remains wide. The chances of surviving a heart attack or stroke are the lowest in the OECD. Children with leukaemia are also much less likely to survive in Mexico than in other OECD countries. More investment is needed to bring health care spending (per capita and as a percentage of GDP) closer to OECD averages. In 2016, Mexico spent just 5.8% of GDP on health care, compared to the 9.0% OECD average. Despite improvements, access to services remains far from equal, with different levels of service between subsystems and individuals' out-of-pocket spending on health care among the highest in the OECD, signalling a failure of current arrangements to provide effective insurance or deliver high-quality services that people want to use. Further structural reform can help reduce differences across the various subsystems and improve equity. Most urgently, concerted effort to improve the quality of care is needed.

**Figure 2.8. Out-of-pocket health spending has fallen, but is still very high by international comparison**  
Change in out-of-pocket expenditure as a share of total expenditure on health

## FOSTERING THE WELL-BEING OF MEXICAN PEOPLE

### A MULTISECTORAL STRATEGY HOLDS PROMISE TO REDUCE OBESITY

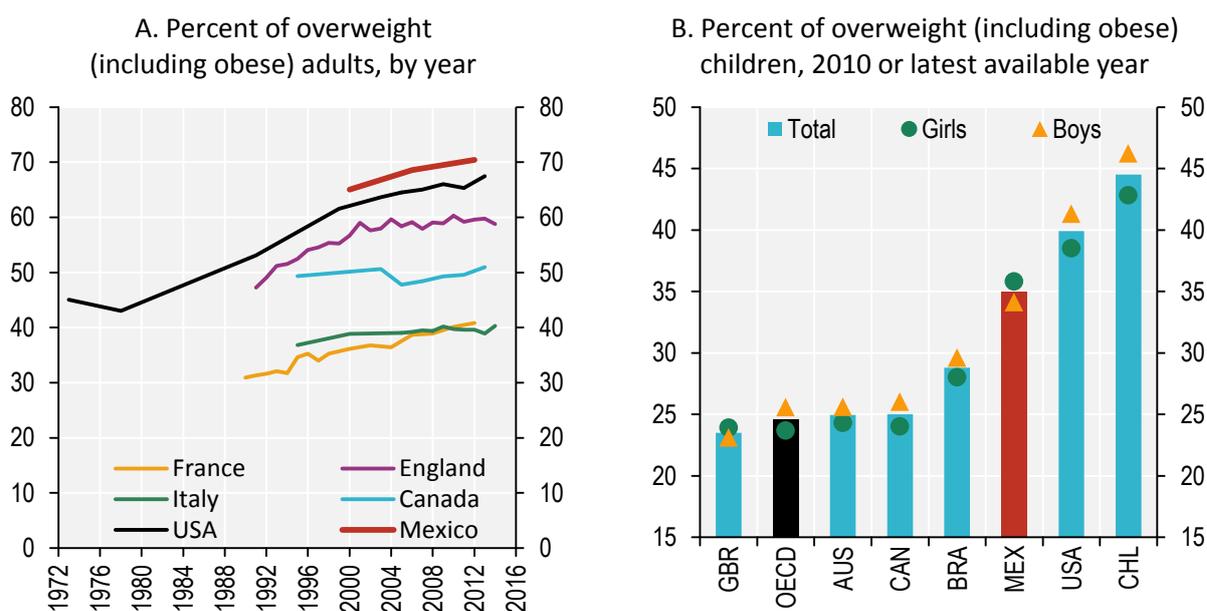

Mexico's low life expectancy relative to other OECD countries is in part due to harmful health-related behaviours such as poor nutrition and high obesity rates (Figure 2.9). Mexico has the second highest obesity prevalence worldwide, with more than one person in three considered obese. Mexico ranks fourth in adolescent obesity among OECD countries.

Mexico's multisectoral strategy to address obesity rates is based on three pillars: public health, medical care, and sector regulation. In particular, the country has introduced measures to increase public and individual awareness of obesity and associated non-communicable diseases. A national programme on healthy eating and physical activity focusses on health promotion and communication. It updated nutritional criteria and guidelines for food and beverages in schools at the national level and enforced strict norms in advertisements targeted at children. It also established specialised obesity and diabetes management units, and addressed legal and fiscal aspects of overweight and obesity. Most famously, in January 2014, Mexico implemented a new tax of 8% on non-essential food with an energy density equal or exceeding 275 Kcal per 100 grams, and 1 peso (EUR 0.06) per litre on sugar-sweetened beverages. The tax was fully incorporated into the final consumer price.

Recent evaluations revealed that purchases of taxed beverages decreased at annual rates between 5.5% and 12% in the first two years after implementation, and taxed food between 5.1% and 10.2% in the first year after implementation. Households at the lowest socio-economic level, which have the highest overweight and obesity rates, reduced their purchases of taxed beverages the most in both years. This suggests that in addition to the effect on purchasing behaviour among households sensitive to price increases, the tax may, together with other measures, contribute to positive health outcomes in the long run.

Mexico is committed to fighting obesity across generations. The OECD's 2010 *Fit not Fat* publication and regular *Obesity Updates* provide comparative statistics and analyses of the impacts of different health interventions.

**Figure 2.9. Obesity remains an important issue in Mexico**

## FOSTERING THE WELL-BEING OF MEXICAN PEOPLE

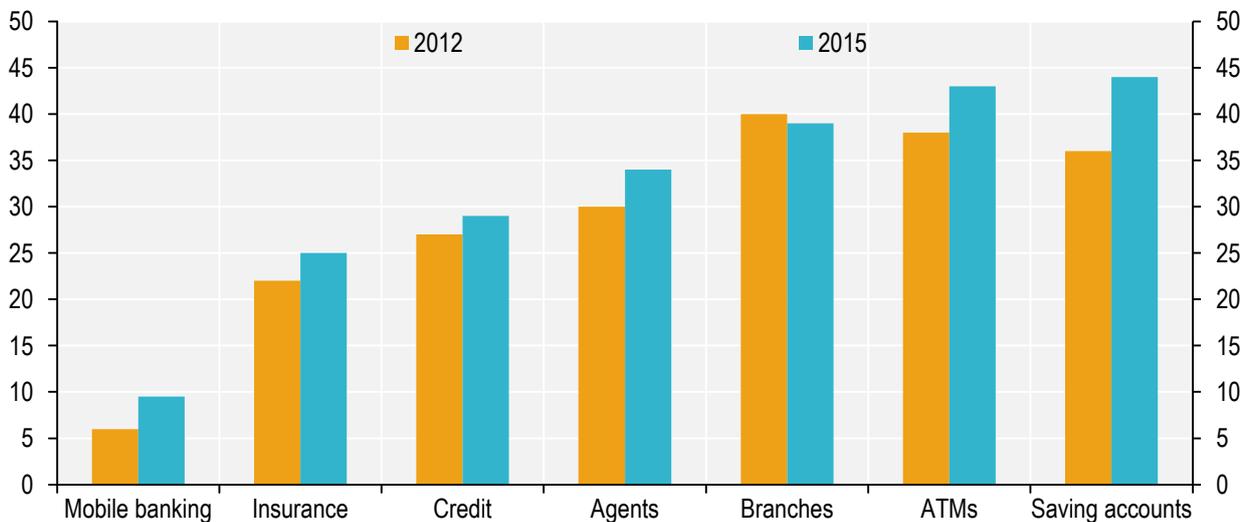

### FINANCIAL REFORM IS CONTRIBUTING TO A MORE INCLUSIVE MEXICO

Mexico's financial sector reform was supported by assessments contained in various editions of OECD *Economic Surveys*. The 2017 edition included a dedicated section on financial inclusion. The 2016 *Pension Review of Mexico* examined, amongst other measures, policy options to increase financial literacy.

A financial sector that lacks scope and breadth not only constrains productivity but also limits the role that consumption and investment smoothing can have in tempering macroeconomic volatility. In 2014, Mexico initiated financial sector reforms aimed at strengthening the regulatory environment, increasing competition, and lowering the costs of borrowing for small and medium-sized enterprises. Reforms also set out to improve Mexico's financial inclusion. Financial inclusion is not only causally related to growth but is also associated with increased levels of self-employment and entrepreneurship, household consumption, and the empowerment of women. Launched in 2014, the Integral Programme for Financial Inclusion provides financial education, credit, programmed savings, insurance and other products and services to beneficiaries of social programmes. In 2016, Mexico's National Financial Inclusion Strategy was finalised.

Thanks to these reforms, the level of credit formalisation has improved, household and corporate sector credit has increased, and the share of people using financial services and financial access points has risen (Figure 2.10). There is still a long way to go, however, as there are still important differences in the accessibility of financial services and access points across Mexican municipalities.

**Figure 2.10. Use of financial services and access points has increased**  
Percentage of adults using a particular financial service or access point

## BOOSTING GROWTH AND COMPETITIVENESS

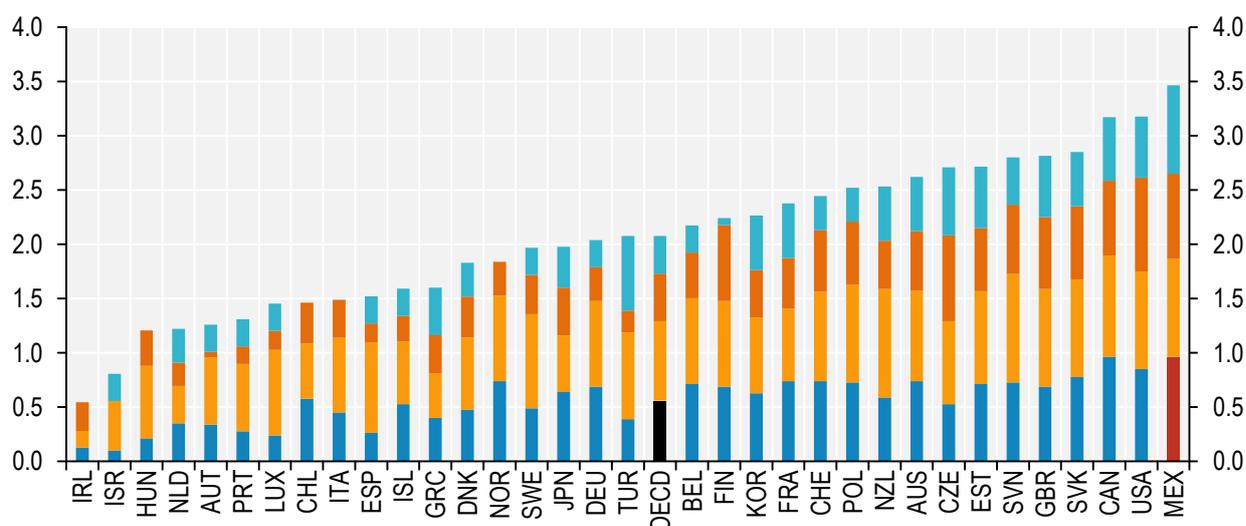

### MEXICO HAS STRENGTHENED ITS REGULATORY FRAMEWORK

To boost economic growth, Mexico embarked on an aggressive programme to reduce administrative burdens (i.e. the time in monetary terms necessary for citizens and businesses to comply with formalities) by 36%, which was finalised by the end of 2016. The government also launched an ambitious initiative to promote regulatory quality at the subnational level. The *Justicia Cotidiana* programme directly engages the federal government with state and municipal governments to simplify business licenses and construction permits, implement commercial oral trials, reduce local administrative burdens and diagnose regulatory reforms in key sectors. A constitutional reform to establish a national policy on better regulation was approved in February 2017. In addition, the system of *ex ante* impact assessment of draft regulations and public consultation in Mexico is performing at a high standard, ensuring that regulations are aligned with their public policy objectives and promote economic activity. Public consultation in this process ensures that stakeholder views are taken into account and helps to gather evidence for effective policy-making. According to the *OECD Regulatory Policy Outlook 2015*, Mexico's stakeholder engagement in the rule-making process is one of the most sophisticated in the OECD (Figure 3.1).

At the same time, challenges such as continuing and deepening efforts to improve regulatory quality at all levels of government remain. A recent assessment by Mexico's Coordinating Council of Businesses rates the average performance of states on regulatory improvement policy at 1.77 and that of municipalities at 1.05 on a maximum scale of 5. The general law derived from the constitutional reform on regulatory improvement remains to be discussed and approved by Congress. In addition, Mexico could further strengthen its consultation system by systematically consulting stakeholders early on to gather opinions on the nature of problems and potential solutions, including through the use of "green papers". Thresholds should be used to trigger *ex post* evaluations of all major regulations and not only technical ones, as is currently the case.

Mexico's actions to strengthen regulatory management are consistent with the recommendations made by the OECD in its 2014 report on *Regulatory Policy in Mexico*. The OECD is also supporting regulatory reform by analysing regulatory barriers to competition in several sectors of Mexico's economy and by working directly with subnational governments to strengthen their regulatory frameworks.

**Figure 3.1. Mexico excels in stakeholder engagement practices**  
Stakeholder engagement in developing subordinate regulations

Note: The vertical axis represents the total aggregate score across the four separate categories of the composite indicators. The maximum score for each category is 1, and the maximum aggregate score for the composite indicator is 4.

Source: *OECD Regulatory Indicators Survey 2014*, [www.oecd.org/gov/regulatory-policy/measuring-regulatory-performance.htm](http://www.oecd.org/gov/regulatory-policy/measuring-regulatory-performance.htm).

## BOOSTING GROWTH AND COMPETITIVENESS

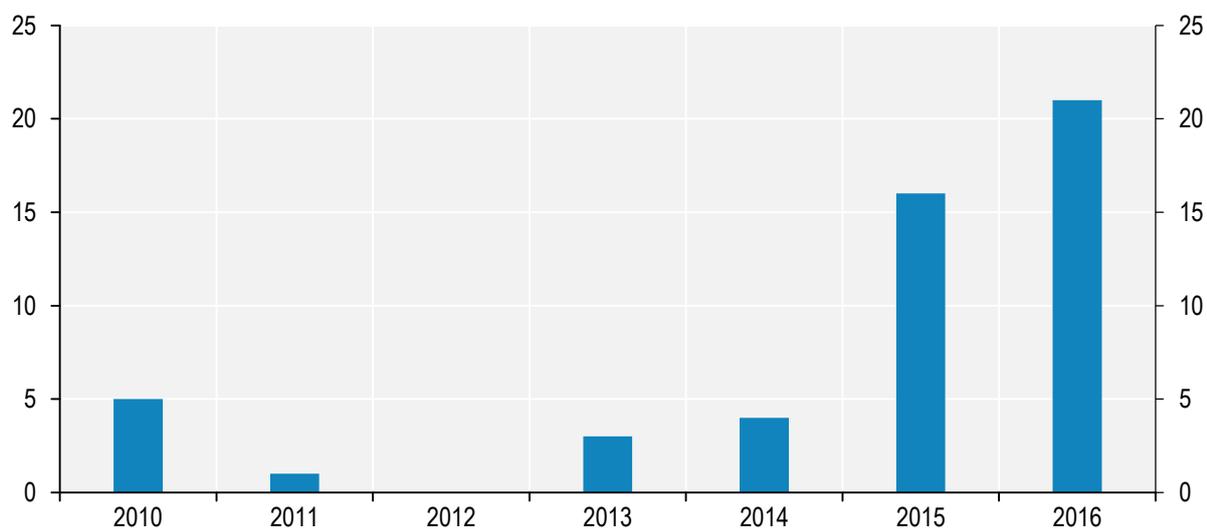

The OECD helped the Mexican government strengthen competition law enforcement through an in-depth analysis of the strengths and weaknesses of the country's competition policy framework presented in its 2012 *Better Policies Series* report. An ongoing OECD project with COFECE aims at further increasing the effectiveness of the agency's actions.

### REFORMS HAVE STRENGTHENED COMPETITION LAW ENFORCEMENT

In 2013, Mexico's Federal Economic Competition Commission (COFECE, in charge of all sectors except telecommunications) was strengthened and transformed into a constitutionally autonomous body with the power to regulate access to essential facilities and remove barriers to competition through broad market investigation powers. The independence, reformed judicial oversight and increased budget followed OECD recommendations and enabled the authority to enhance implementation of recently acquired powers to make "dawn raids", unannounced site inspections to search for documents. The 2013 reforms also established the Federal Institute of Telecommunications, an independent entity for the regulation of telecommunications, including competition law enforcement.

Absolute monopolistic practices are often considered as the highest crime under competition law. They encompass a broad spectrum of wrongdoing stemming from companies agreeing with each other in order to restrict competition. Agreements can focus on price, quantity, market allocation and other key facets of competition. Preventing such conduct is important, as such practices have been shown to increase average prices between 20% and 30%. The successful prosecution of economic cartel cases is time-consuming and depends on clear and convincing evidence. While the number of cases leading to charges has not increased substantially in the last few years (which is understandable, as cases often take three or more years to investigate), the number of dawn raids has increased substantially (Figure 3.2). The 2013 reforms have therefore yielded substantial benefits for competition law enforcement in Mexico.

**Figure 3.2. The number of dawn raids increased significantly following the 2013 reforms**  
Unannounced site inspections conducted by COFECE, by year

## BOOSTING GROWTH AND COMPETITIVENESS

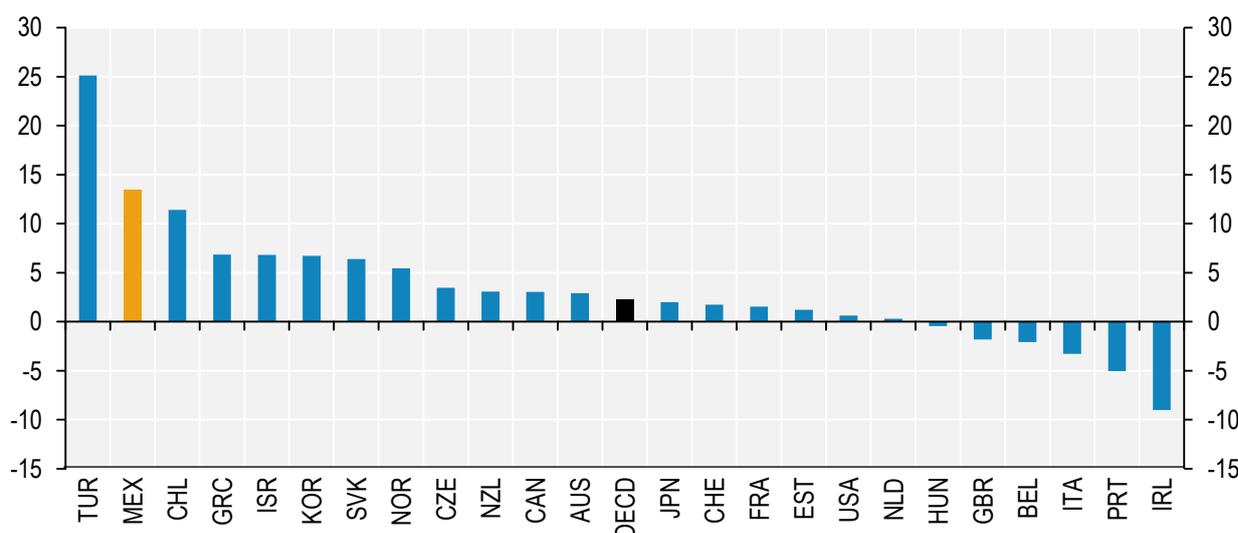

### MEXICO HAS RECOGNIZED THE IMPORTANT ROLE OF SMALL AND MEDIUM-SIZED ENTERPRISES FOR INCLUSIVE GROWTH

Small and medium-sized enterprises (SMEs) are at the centre of Mexico's Programme to Democratise Productivity, a range of reforms which have contributed to a better business environment (Figure 3.3). Early in its mandate, the Peña Nieto administration established the National Institute of the Entrepreneur (INADEM), responsible for the design, co-ordination and implementation of federal SME and entrepreneurship policies. The creation of INADEM has helped to improve the coherence of SME policies and increase government attention to new and small business development. Moreover, Mexico's efforts to increase transparency in its Entrepreneur Fund – the main source of programme funding for SMEs – constitute a best practice and are in line with the recommendations of the OECD's 2013 review of SME and entrepreneurship policies in Mexico. For example, project proposals are selected by an independent evaluation panel according to clear and publicly available selection criteria, and the names of government-supported enterprises are published online. In 2017, the Entrepreneur Fund was ranked at the top of Mexico's Index of Performance of Federal Public Programmes.

The OECD advised the Mexican government on its strategic approach to SME policy and provided comparative analyses of good practices for enhancing productivity in small enterprises in traditional sectors.

Mexico's SME policy has focused both on boosting productivity in very small enterprises in traditional industries (e.g. retail trade), and on fostering high impact entrepreneurship. In the first case, policy support has taken the form of business incubators for basic enterprises, a micro-franchise support programme, and a large-scale programme encouraging both the upgrading of managerial skills and ICT adoption. In addition, the 2013 reform of the corporate fiscal regime aims at fostering small business formalisation by offering discounted rates, over a 10-year period, on the personal income tax rate of small business owners whose annual revenues are less than MXN 2 million. As part of efforts to foster high-growth SMEs, Mexico has provided support to a network of business incubators and accelerators working with promising start-ups and growth-oriented SMEs and set up 40 public-private venture capital funds.

**Figure 3.3. Loans to SMEs have grown at a sustained pace**  
Average annual growth rate in outstanding SME loans, 2012-15

Note: Average annual growth rate of outstanding SME loans (adjusted for inflation) in the period 2012-2015.

Source: OECD (2017), *Financing SMEs and Entrepreneurs 2017: An OECD Scoreboard*, [http://dx.doi.org/10.1787/fin\\_sme\\_ent-2017-en](http://dx.doi.org/10.1787/fin_sme_ent-2017-en).

## BOOSTING GROWTH AND COMPETITIVENESS

### TELECOMMUNICATION AND BROADCASTING REFORM HAS INCREASED ECONOMIC COMPETITIVENESS AND SOCIAL WELL-BEING

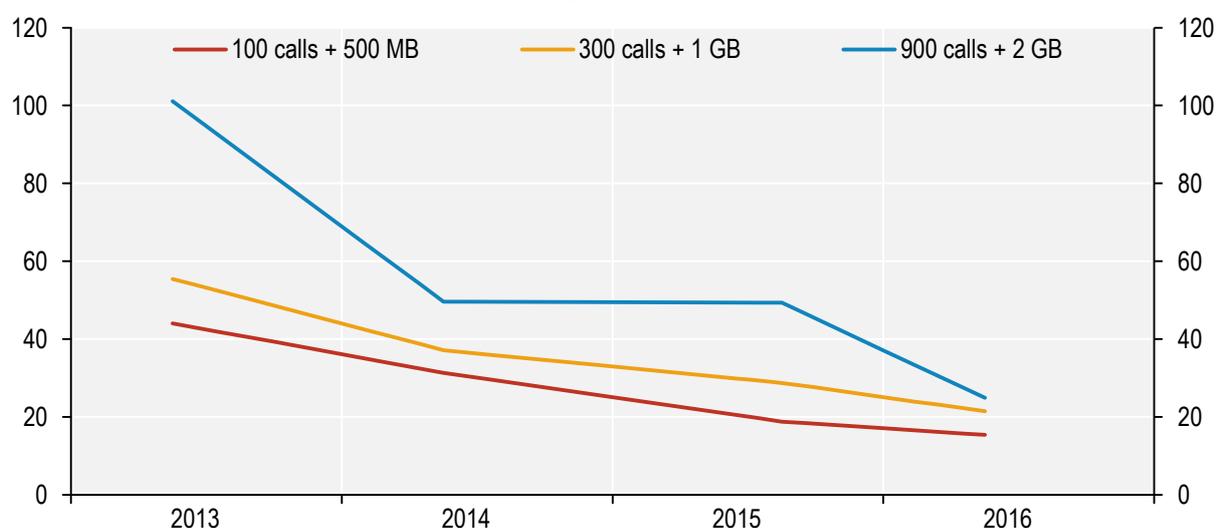

The OECD's 2012 *Review of Telecommunication Policy and Regulation in Mexico* made 31 recommendations to improve Mexico's legal and regulatory framework, 28 of which have been fully implemented. The other three have either been partially implemented or are in the course of being implemented. In 2016, Mexico hosted the OECD Ministerial Meeting "Digital Economy: Innovation, Growth and Social Prosperity", which put forward directions for public policies to foster the development of the digital economy.

The 2013 telecommunication and broadcasting reform triggered an important modernisation of both sectors. The results, illustrated in the 2017 *OECD Telecommunication and Broadcasting Review of Mexico*, have been remarkable. The number of mobile broadband subscriptions rose from 24 million in 2012 to over 74 million in 2016. Prices for mobile telecommunication services declined by 61% for the OECD medium-usage basket and by 75% for the OECD high-usage basket (Figure 3.4). Both the telecommunication and broadcasting sectors experienced significant growth and foreign competitors have entered the telecommunication and satellite markets. Investment in telecommunication has increased. The *Red Compartida* – a shared wholesale wireless network – will likely further spur investment. Mexico completed the switchover from analogue to digital television, freeing up spectrum for mobile communication services, and licensed a third national free-to-air television network.

To further promote competition, following the regulator's 2017 preponderance review, the Federal Telecommunications Institute imposed new remedies to the preponderant agent, including mandatory functional separation between the wholesale and retail operations of the fixed-service provider (Telmex-Telnor). These measures have opened networks to other firms, which will stimulate the development of both fixed and mobile communication services.

It is now crucial for Mexico to maintain reform momentum and further encourage competition, including by reducing the regulatory burden for Telmex-Telnor to address the high market concentration in pay-TV and broadcasting. Market conditions could be further enhanced by abolishing the special tax on telecommunication services. Mexico would also benefit from a better alignment of the roles of different authorities in formulating and implementing digital economy policies.

**Figure 3.4. Prices for mobile broadband services fell sharply after the reform**  
Mobile broadband prices in Mexico, USD PPP

## BOOSTING GROWTH AND COMPETITIVENESS

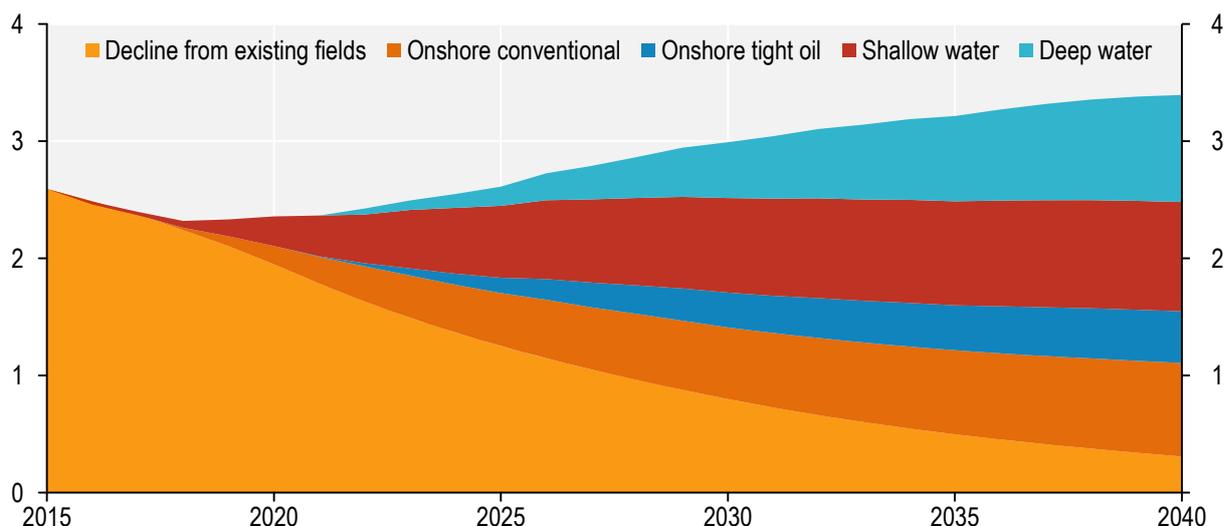

### MEXICO'S 2013 ENERGY REFORM IS A LANDMARK IN THE ENRIQUE PEÑA NIETO PRESIDENCY

After years of declining oil production, high electricity production costs and a lack of funding and technology to exploit new energy resources, Mexico has opened up its long-closed oil, gas and electricity sectors to private operators. Oil production prices have been liberalised, allowing market entry by both domestic and foreign investors in the exploration, production and transportation of oil by-products and gas, as well as the refining and marketing of hydrocarbons. Governance of the state-owned petroleum company PEMEX has been strengthened with the appointment of independent directors responsible for establishing its strategic vision. Existing sector regulators have been granted new powers and status, including legal independence and budgetary autonomy, and new ones have been created. Deep reforms have also reorganised the electricity sector. Competition from new entrants is now allowed. The state-owned power enterprise CFE has been completely unbundled, effectively ending its monopoly. The auction system for renewables is a world reference and has attracted some of the lowest price projects globally.

The reform has been a great success, boosting private investment, energy production (Figure 3.5), technological know-how, tax revenue, and business confidence. Improved access to US shale gas has allowed Mexico to rapidly move from costly and polluting oil-fired electricity generation to gas. The transition to a different energy mix will also contribute to improving Mexico's environmental performance. Continued success of the energy reform hinges on consolidating the independence of sector regulators and more focus on long-term planning to support stable regulatory activity.

*Mexico's energy reform is in line with recommendations made in the OECD's Economic Surveys. The OECD has supported the government in the area of energy policy through its 2017 Performance Reviews of Mexico's three energy regulators, the 2017 Public Procurement Review of PEMEX, and the IEA report Energy Policies Beyond IEA Countries: Mexico 2017.*

**Figure 3.5. Thanks to the energy reform, oil production is expected to increase again**  
Oil production in Mexico in the New Policies Scenario, in millions of barrels per day, 2015-40

## PROTECTING MEXICO'S ENVIRONMENT

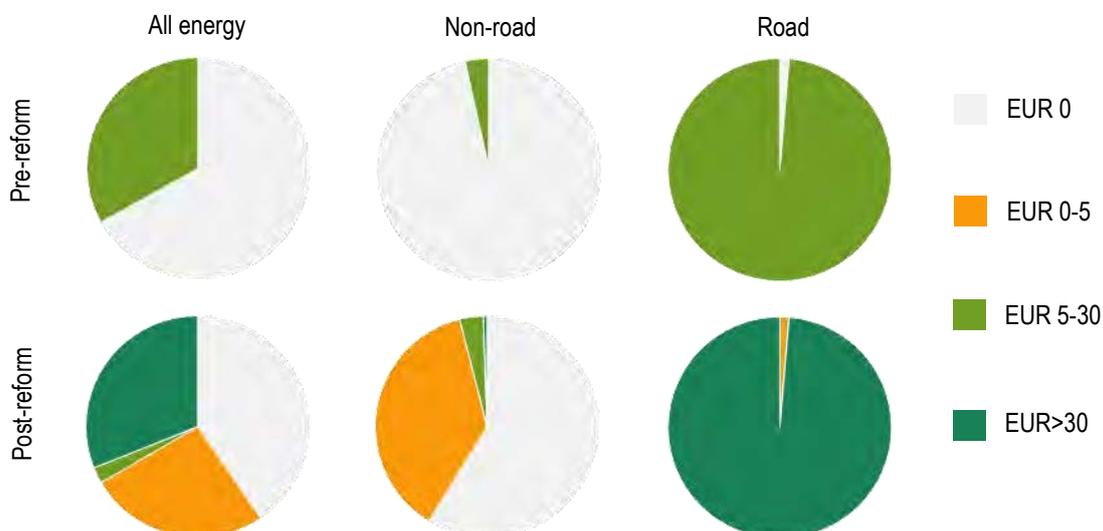

### MEXICO HAS MADE IMPORTANT PROGRESS ON FIGHTING CLIMATE CHANGE

Mexico's environmental reforms are in line with OECD recommendations. The OECD's 2013 Environmental Performance Review of Mexico recommended the introduction of an excise tax on transport fuels and energy products reflecting the environmental costs associated with their use, and providing targeted cash transfers to those adversely affected.

Mexico was the first emerging country to submit its nationally determined contribution (NDC) ahead of the UNFCCC COP21. It ratified the Paris Agreement on 16 September 2016. The government committed unconditionally to reducing greenhouse gas emissions (GHGs) and short-lived climate pollutants, implying a 22% reduction of GHGs and a 51% reduction of black carbon, relative to business-as-usual levels, by 2030. Further reductions of up to 36% and 70%, respectively, could take place under certain conditions. Furthermore, Mexico is one of only six countries to have submitted a long-term low-GHG development strategy. In its 2015 Energy Transition Law, Mexico confirmed its 2024 clean energy target of 35% and introduced intermediate targets. Changes to the climate change law now mandate the creation of a cap-and-trade system. Mexico has also strengthened the recognition of resilient ecosystems as a means to reduce adverse impacts of climate change.

However, efforts are still needed to achieve these targets, given rapidly growing emissions from the energy and transport sectors (the latter being an important source of air pollution). Significant steps were taken in 2014, when Mexico moved away from transport fuel subsidies and increased excise tax rates on transport fuels. A new carbon tax was simultaneously introduced (including on fuels outside of the road sector), improving the extent to which the external costs of energy use are reflected in prices (Figure 4.1), but rates are very low. Progressively increasing carbon taxes and ensuring that rates more uniformly reflect the carbon content of fuels would send a strong price signal of the external costs of carbon emissions. The gradual implementation of the reforms had initially increased their political acceptability, but increasing tax rates further may necessitate social transfers for those affected by the increase in energy prices. Mexico should develop estimates of the cost effectiveness of the various mitigation instruments on a cost-per-tonne of CO<sub>2</sub> basis, both in terms of short-term reductions and in delivering the 2030 target. Falling costs of renewable technologies provide an opportunity to accelerate decarbonisation of the electricity supply.

**Figure 4.1. Mexico increased the share of emissions covered by a carbon price, but at low rates**  
Percentage of carbon emissions priced at different levels

## PROTECTING MEXICO'S ENVIRONMENT

### ACCESS TO DRINKING WATER AND SANITATION HAS IMPROVED

Mexico has made considerable progress in improving access to drinking water (Figure 4.2) and sanitation and in reducing water-related diseases. The government has also taken steps to raise the efficiency of water use. Water use tariffs have been significantly increased since 2014, and incentives to better use and treat water have been introduced. The 2013 energy reform facilitated investment in water-efficient practices in the electricity sector. The National Water Reserves Programme was established to help ensure future water availability. The Rain Harvest and Ecotechnics National Programme aims at strengthening water management in Mexico's poorest rural areas. Internationally, Mexico has played a key role in promoting a new approach to water management, including in the High-level Panel on Water.

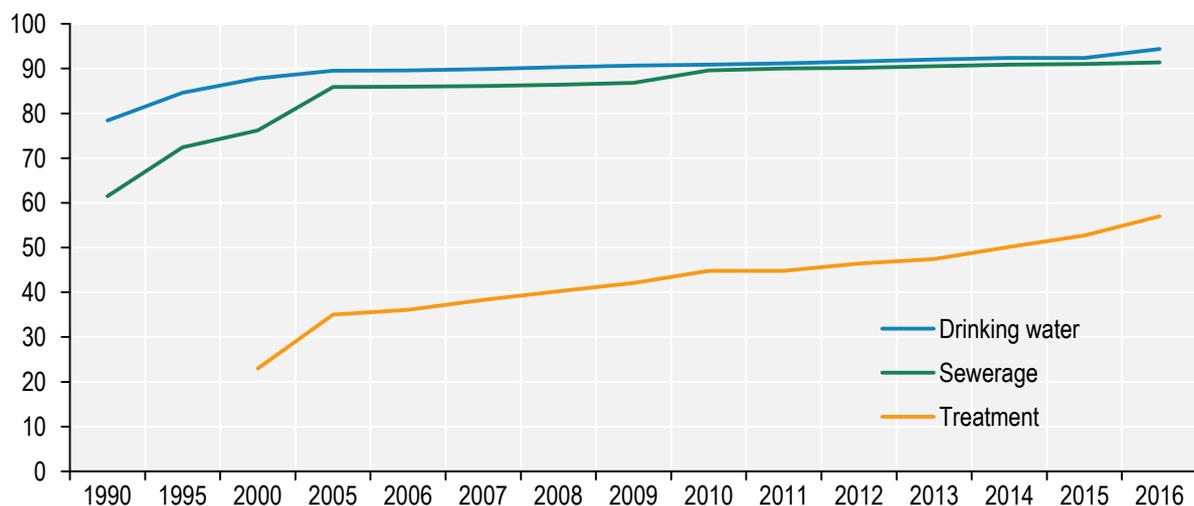

Due to population growth, water management remains an ongoing challenge. Over the next two decades, Mexico will have to provide an additional 36 million people with drinking water and 40 million people with sanitation services. In addition, Mexico still has the lowest rate of connection to public wastewater treatment plants in the OECD. The government has put in place instruments to tackle these issues. The Social Infrastructure Fund supports local and state governments in developing basic social infrastructure, including drinking water and sanitation.

Building on recent progress, Mexico needs to promote water use efficiency across sectors, allocate water where it creates most value and encourage investment in water infrastructure. This requires addressing multi-level and river basin governance challenges to reduce inconsistencies between federal and basin priorities, strengthening the role, capacity, prerogatives and autonomy of river basin councils and establishing platforms to share good practices. Removing overlaps and gaps in regulatory functions is also key. Mexico needs to better ensure consistencies across water, agriculture and energy policies and phase out subsidies for water pumping and fuel used to pump groundwater, instead considering direct income support where needed. Adjusting water allocation regimes can also help promote water use efficiency within and across sectors. Water service tariffs need to be raised further to reflect operation and maintenance costs and improve water bill collection.

The 2013 OECD report *Making Water Reform Happen in Mexico* provided evaluations and recommendations in support of Mexico's water policy reforms. The related *Policy Dialogue* consulted over 100 stakeholders at federal, state and basin level.

## PROTECTING MEXICO'S ENVIRONMENT

The OECD helped the Mexican government in its endeavour to protect the country's biodiversity through the 2013 *Environmental Performance Review*, which examined Mexico's institutional and policy framework for the conservation and sustainable use of biodiversity resources and provided recommendations for a more co-ordinated, coherent and strategic approach.

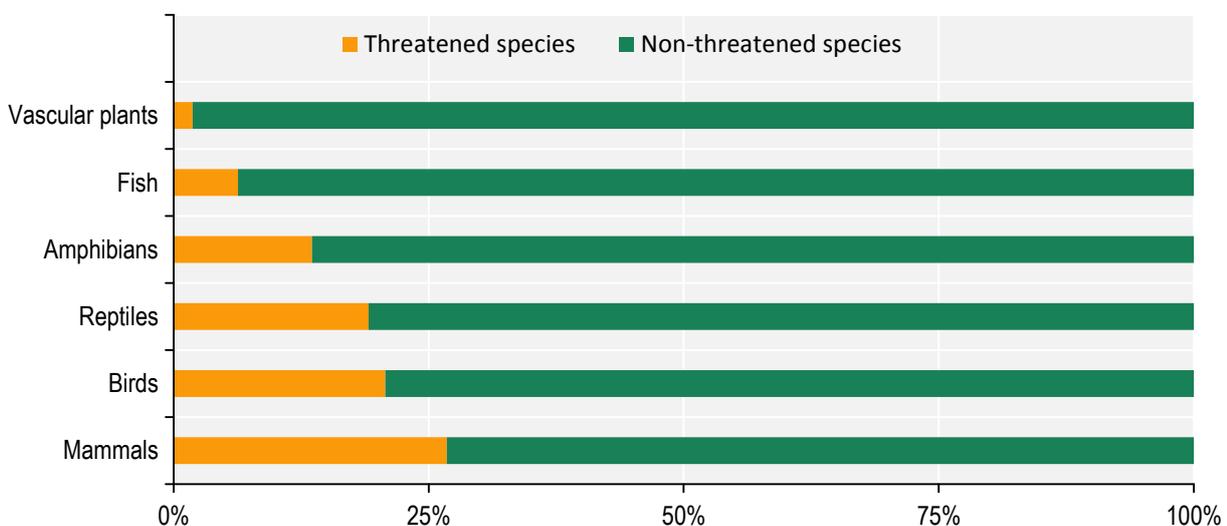

### MEXICO HAS MADE CONSIDERABLE PROGRESS IN PROTECTING ITS BIODIVERSITY

Mexico is a mega-diverse country, home to 10-12% of the world's biodiversity and a large number of threatened species (Figure 4.3). Biodiversity has been under pressure from land use change and deforestation, overexploitation, invasive alien species, pollution and climate change. As these pressures are linked to policies in other sectors, mainstreaming biodiversity is crucial to conservation and sustainable use.

The government has made notable progress in better protecting biodiversity through laws, strategies and programmes, together with strong institutions. Between 2009 and 2015, 11 new protected areas were established, increasing coverage to 91 million hectares (comprising 21 terrestrial and 70 marine protected areas). Mexico now protects 23% of its coastal and marine areas, exceeding the Aichi target of 10%. A commitment to further increase protection has been cemented in Mexico's National Biodiversity Strategy and Action Plan 2016-30. Under this plan, extensive action was taken to create new Marine Protected Areas (MPAs), increasing total coverage to over 700 thousand km<sup>2</sup>. The Revillagigedo National Park is now the most extensive fully protected marine area in North America. Mexico also uses a range of other policy tools to conserve and sustainably use biodiversity, including subsidies (many of which aim at improving the conditions of local and indigenous communities) and payment for ecosystem services (PES). Mexico's PES programme covers 3.25 million hectares of forest and is one of the world's largest.

It is important for Mexico to strengthen its institutional framework for biodiversity management by establishing a high-level interministerial task force and to reform environmentally harmful government support in sectors such as agriculture and fisheries (e.g. agricultural subsidies that promote land-use change, VAT exemption on agrochemicals, electricity subsidies for agriculture, and fuel subsidies for fisheries). Mexico would also benefit from streamlining programmes to support indigenous people and the environment, increasing the focus on capacity building and achieving social and environmental objectives more efficiently.

**Figure 4.3. Mexico is home to a large number of threatened species**  
Percentage of all species in a given category, 2016 or latest available year

Note: Threatened species are defined as IUCN Categories "critically endangered", "endangered" and "vulnerable".

## STRENGTHENING MEXICO'S GOVERNANCE SYSTEMS

### IMPORTANT STEPS HAVE BEEN TAKEN TO IMPROVE THE JUDICIAL SYSTEM

Mexico's justice system faces immense challenges in terms of credibility, effectiveness and timeliness. To better meet justice needs, Mexico has amended its constitution and other laws to facilitate the enforcement of constitutional rights. Laws now ensure that judges give priority to analysing the motives behind disputes rather than to the formalities of the proceedings. Moreover, citizens are now able to file claims online.

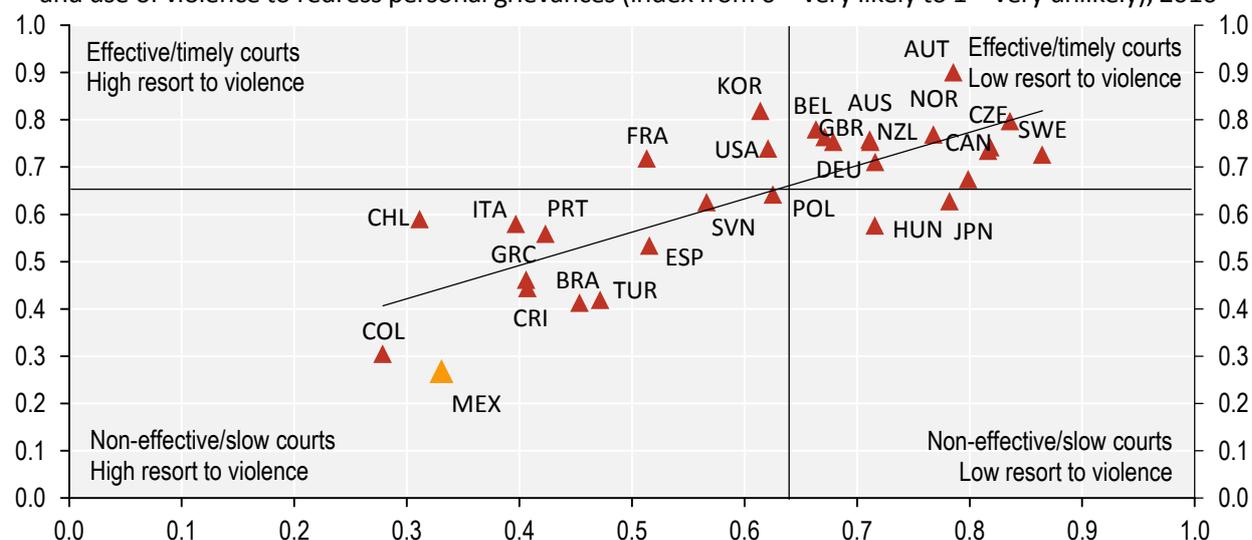

Mexico also profoundly changed its criminal justice system, which is key to improving personal safety and overall well-being and the rule of law (Figure 5.1). 2016 saw the launch of the new adversarial criminal justice system after eight years of implementation. A unified National Code of Criminal Procedure (now to be applied at federal and state levels) was passed to make sure the right of due process is well protected. Victims now have a formal and relevant role in their cases and the length and fairness of procedures has improved substantially.

To improve everyday justice, the *Justicia Cotidiana* initiative, an innovative and extensive consultation process to understand and address the daily legal needs of citizens and businesses, was launched in 2014. This led to reforms aimed at making rules simple to understand, encouraging the use of alternative dispute settlement mechanisms, automating procedures and reducing red tape. For example, to enhance court efficiency and contract enforcement, orality was introduced in commercial proceedings at the first instance. According to the Federal Commission for Regulatory Improvement, the reduction of the number of proceedings since 2011 in Mexico City (from 38 to 21) coincided with a drop in their length (from 400 to 270 days). In 2013, reform to economic and fiscal shelters and the establishment of nationwide specialised jurisdictions in competition, telecommunication and broadcasting aimed at raising the quality of judicial decisions, reducing the length of judicial review and giving effect to competition reforms more broadly. Addressing the lack of training of criminal justice stakeholders (police, lawyers, judges and staff) is now crucial.

To support Mexico's justice system reform, the OECD worked with Mexico's Institute for Competitiveness to assess the country's policy-making cycle.

**Figure 5.1. Personal safety is strongly linked to the effectiveness of the justice system**

## STRENGTHENING MEXICO'S GOVERNANCE SYSTEMS

### THE ANTI-CORRUPTION AGENDA IS MOVING IN THE RIGHT DIRECTION

The *OECD Integrity Review of Mexico* provided over 60 proposals for action to improve the integrity of Mexico's public sector. In addition, the OECD has been working with several federal states, including Coahuila, Nuevo León, Sonora, and Mexico City, to strengthen their integrity frameworks and public procurement practices. Working with COFECE, the OECD has also carried out several projects to help fight bid rigging in public procurement, notably in the healthcare and energy sectors.

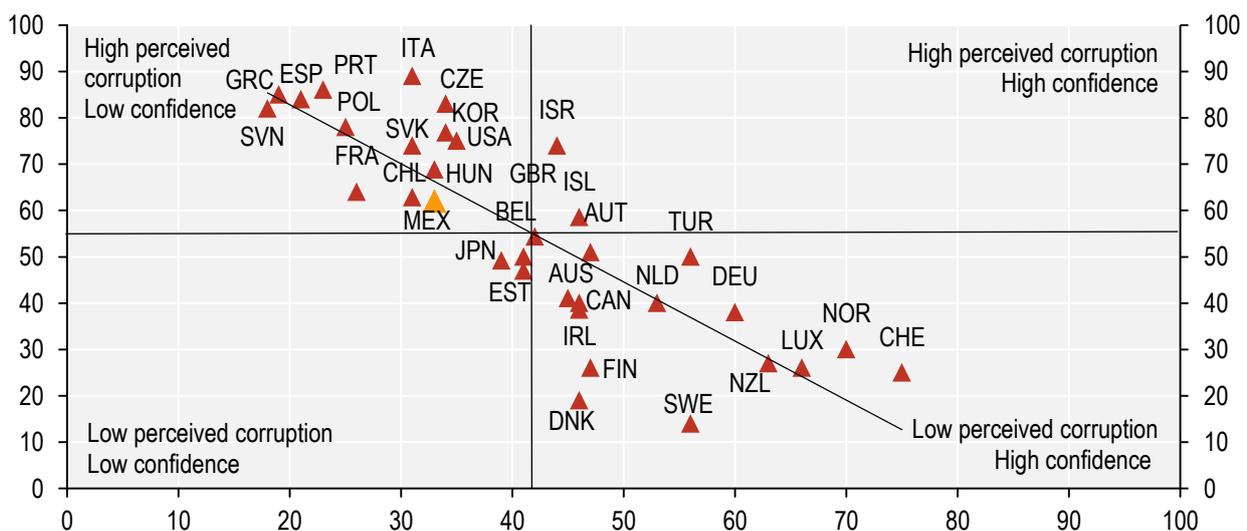

While fighting corruption has long been a priority of Mexico, its policymakers have, at times, come up short in passing effective long-term reform. Under the leadership of President Peña Nieto, Mexico has taken steps towards a major overhaul of its institutional and legal frameworks.

The National Anti-corruption System (SNA) was created to improve and facilitate co-ordination in the prevention, detection and sanctioning of corruption. The General Law of Administrative Responsibilities (GLAR) was published, heightening penalties for firms and individuals that engage in corruption or commit administrative violations. The GLAR promotes public transparency by obliging public servants to disclose their tax returns, submit asset declaration statements and declare conflicts of interest. It established a national auditing system to harmonise anti-corruption and integrity policies and capacities across Mexico. Guidelines for companies seeking to implement anti-corruption compliance programmes and codes of conduct were established. The Integral System of Citizen Complaints was launched, allowing citizens to submit complaints and allegations of corruption online and to follow cases until their conclusion. The Code of Ethics for federal public servants and the Rules of Integrity for the Exercise of Public Functions show that Mexico is committed to developing civil servants that comply with the principles of legality, honesty, loyalty, impartiality and efficiency.

While these reforms created a good foundation to fight corruption, implementation is still a work in progress. Mexico is in the midst of appointing several key positions, including the Anti-corruption Attorney, and states are developing the necessary legal reforms to implement local anti-corruption systems. In co-ordination with the OECD, the Ministry of Public Administration has designed an Action Plan which assigns responsibilities for implementing each of the recommendations made in the *OECD's Integrity Review of Mexico*, together with a calendar to monitor compliance.

**Figure 5.2. Corruption and trust in government are strongly linked**

## STRENGTHENING MEXICO'S GOVERNANCE SYSTEMS

### MEXICO HAS GREATLY INVESTED IN OPEN GOVERNMENT REFORMS

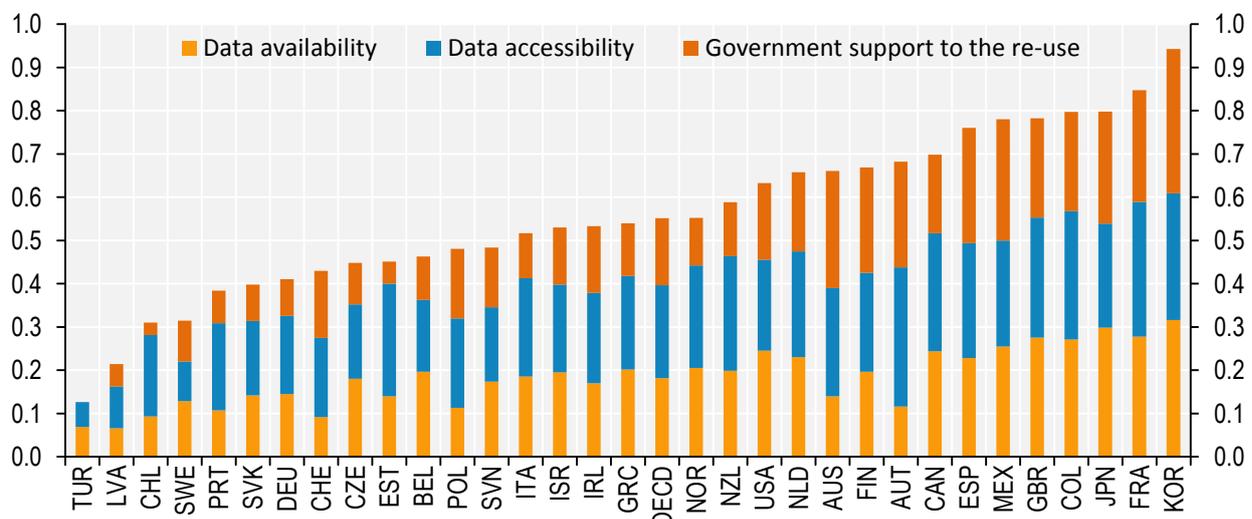

Mexico was one of the first countries to fully link its national development, public reform, open government and digital agendas. The National Development Plan 2013-18 includes open government as an objective and open data as a transversal enabler. Mexico has pioneered involving other branches of power, subnational governments and independent state institutions in open government processes, creating the Open Mexico Network and the Alliance for an Open Mexican Parliament in 2014. The country has further expanded its legal framework for open government. In 2015, the General Transparency Law was approved, requiring state authorities in all branches, autonomous organisations, trade unions and any other entities dealing with public funds to make all information generated public. The law also strengthened the role of the National Institute for Transparency, Access to Information and the Protection of Personal Data.

The Office of the President's leadership since 2013 in co-ordinating the National Digital Strategy has been critical in fostering the development of open data initiatives both nationally and internationally. The 2015 Executive Decree on Open Data was an important sign of high-level political support. As a result of these efforts, Mexico now ranks among the top 5 OECD countries in the OECD's OURdata Index (Figure 5.3).

Despite this impressive progress, there is scope for more improvement, especially by further institutionalising the country's efforts. This includes consolidating the role of the national open government co-ordinator and elaborating a fully-fledged national open government policy to make open government a cross-cutting instrument to address socio-economic challenges. Potential also remains to further foster public sector efficiency and innovation and strengthen the economic and social impact of policy through open data related projects. To this end, it is necessary to further strengthen open data policies, develop data and digital literacy among citizens and businesses, and foster partnerships with the private and academic sectors. It is also crucial to further develop improve impact evaluation of open government initiatives and to use open data for evidence-based policy-making in broader sectoral policy goals such as civil protection and risk management.

**In pushing forward its open government agenda, Mexico has benefitted greatly from peer learning with other OECD countries. For example, Mexico is the co-chair of the OECD Network on Open and Innovative Government in Latin America and the Caribbean. In 2016, Mexico led the initiative on 'what works and doesn't work' in digital service delivery of the Working Party of Senior Digital Government Officials.**

**Figure 5.3. Mexico has made great strides towards open government data**

## STRENGTHENING MEXICO'S GOVERNANCE SYSTEMS

### IMPROVING THE EFFECTIVENESS

#### OF STATE AND LOCAL GOVERNMENTS REMAINS CHALLENGING

**Mexico's ambition to strengthen the effectiveness of state and local governments will benefit from several OECD reviews, including *Territorial Reviews* of Morelos, Valle de México, Puebla-Tlaxcala and Chihuahua. The 2015 *Urban Policy Review of Mexico* includes an examination of subnational capacity issues for urban development.**

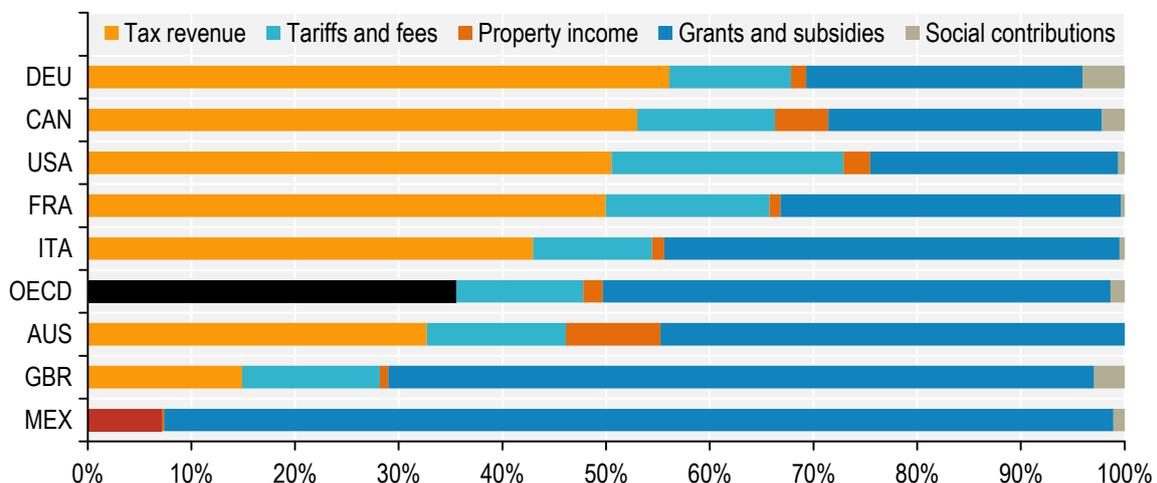

Mexico's National Development Plan 2013-18 stressed the importance of involving all sectors and levels of government in fostering national development and productivity. Subnational governments need clear competencies and responsibilities, together with adequate capacity, to fulfil this role. States and municipalities are responsible for 50% of total public expenditure, in line with the OECD average of federal countries. The difference between taxing power and spending responsibilities is significant compared to the rest of the OECD, however. Mexico's subnational governments have a low share of resources from tax revenue, among the lowest of OECD countries (Figure 5.4).

With the amendment of the Law of Fiscal Co-ordination, which included the creation of a Programme of Institutional Development, the government has steered Mexico towards improving fiscal federalism relations. Still, Mexico remains a centralised country. Large spending areas are controlled by the federal government. Local government expenditure and investment shares in GDP and public spending are among the lowest in the OECD. At the same time, the distribution of functional responsibilities across levels of government is complex, undermining the effectiveness of policy delivery and public investment. Federal powers are extensive and sometimes overlap with responsibilities of states and municipalities. The inability to re-elect municipal leaders for more than one term has caused frequent changes in priorities. During the Peña Nieto administration, re-election has become possible, which will help improve subnational government capacity and effectiveness.

Mexico needs to redefine responsibilities across levels of government to improve policy delivery, along with adequate resources. It would also benefit from improved subnational governance to raise the impact of public investment. Indeed, OECD evidence shows that the quality of subnational governance is directly connected to investment outcomes. The most efficient way to achieve greater economic and social cohesion is by improving the quality of government.

**Figure 5.4. States and municipalities funded mostly through grants and subsidies instead of taxes**

## STRENGTHENING MEXICO'S GOVERNANCE SYSTEMS

### DISASTER RISK MANAGEMENT CONTINUES TO IMPROVE

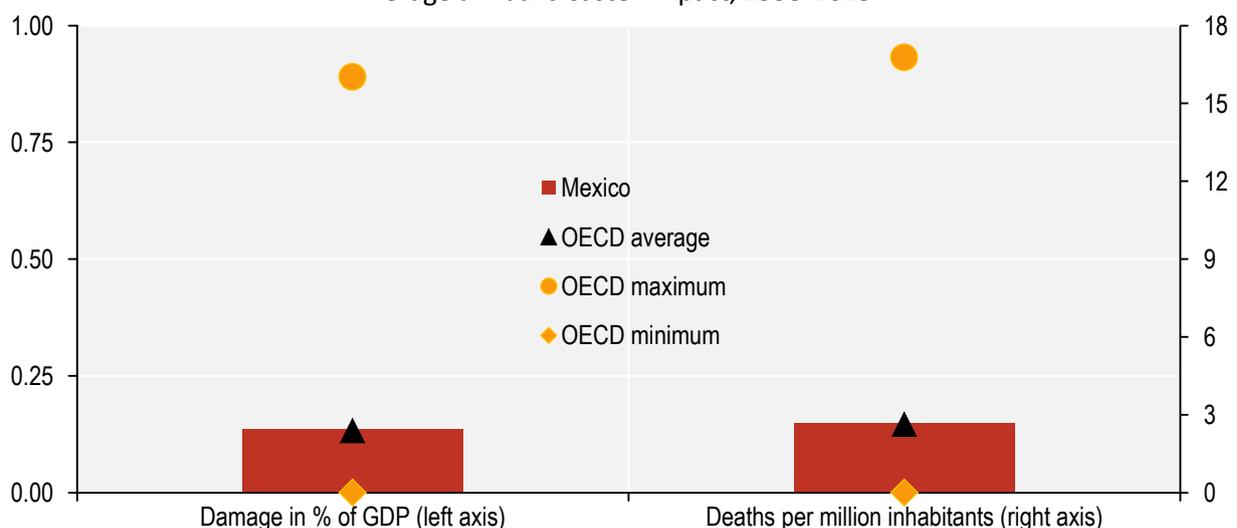

Mexico is acutely aware of its significant exposure to natural hazards (Figure 5.5). The National Civil Protection System was created in 1986 and gradually strengthened over time, putting greater focus on risk prevention. Several additional tools have been launched since 2013. The Digital National Risk Atlas and the National Atlas of Vulnerability to Climate Change inform citizens and firms about natural risks. The General Law of Human Settlements, Territorial Planning and Urban Development puts local governments in charge of administrating and approving the zoning of population centres in their territories. In September 2017, the operating rules of the National Fund for Natural Disasters were changed to better support private stakeholders in recovering from disasters. The Special Climate Change Programme 2014-18 sets out measures to raise resilience to climate change.

Response to the earthquakes that struck the capital in 2017 demonstrated the remarkable resilience that Mexico has achieved through its reforms. The events proved the effectiveness of early warning systems, usefulness of hazard maps and availability of comprehensive building codes, in addition to efficient financial management, interinstitutional co-ordination between federal ministries and international emergency support. All these factors helped save lives and limit economic disruptions. The strong volunteer network that supported public response and recovery efforts illustrated Mexico's society-wide culture of risk.

Still, the recent earthquakes underlined persisting challenges. Co-ordination gaps between emergency response stakeholders and across levels of government and with civil society hampered a more effective response. Despite changes to construction regulation after the 1985 earthquake, breaches and shortcomings in building inspections and construction monitoring contributed to building collapse. The earthquakes also showed that land use and urban planning do not take risk information sufficiently into account. Improving the monitoring and evaluation system to assess progress on climate change adaptation and land use planning could also help to increase resilience.

**The OECD supported the Mexican government in strengthening its disaster risk management through the 2013 Review of Disaster Risk Management Policies, which provided an overview of the challenges faced by SINAPROC as well as an agenda for action.**

## STRENGTHENING MEXICO'S GOVERNANCE SYSTEMS

Close co-operation with the OECD has improved transparency in public procurement, one of the most critical elements determining efficiency and quality in infrastructure delivery. The OECD also works with the Mexican government in the delivery of the New National Airport of Mexico City.

### INFRASTRUCTURE GAPS ARE CLOSING AND GOVERNANCE HAS IMPROVED

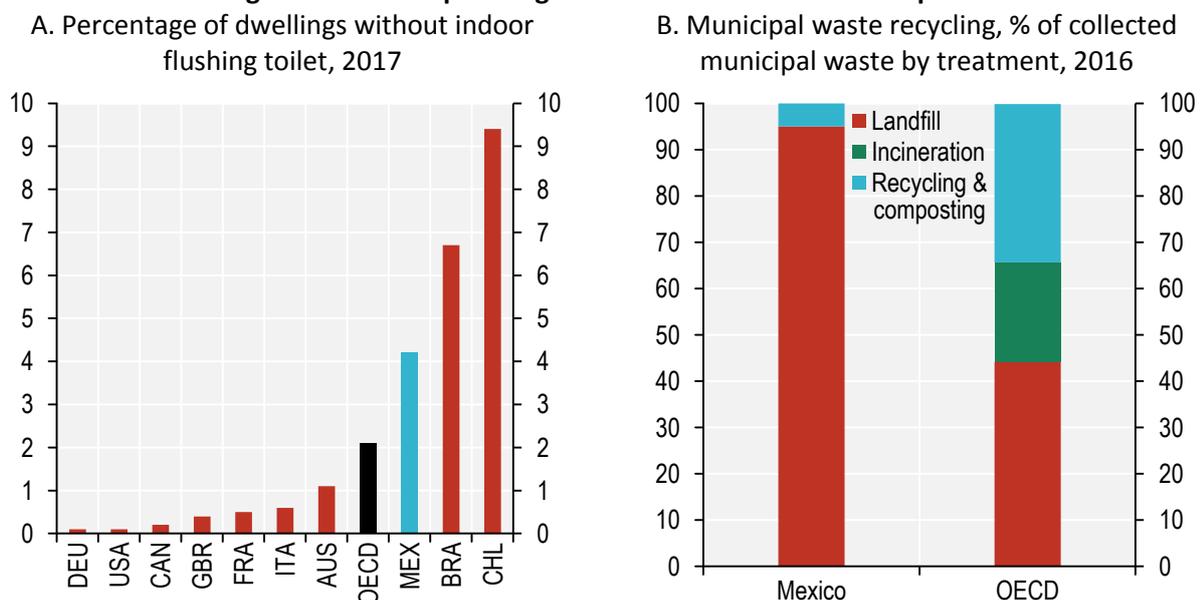

The Peña Nieto administration has taken important steps to strengthen public policies in various areas, from freight transport to housing, public procurement, risk management, ethics and conflict of interest, up to the effective development of mega-projects such as the New International Airport of Mexico City.

Past housing development often occurred in places lacking basic facilities, leaving many low and lower-middle income families with inadequate services (Figure 5.6, panel A) and poor access to good schools, hospitals and employment opportunities. Since 2013, the situation has improved, with 8 out of every 10 houses built within urban containment perimeters. The National Housing Programme 2014-18 intends to address geographical segregation by socioeconomic status by narrowing the gap in good quality housing, improving interinstitutional co-ordination in urban services delivery and moving to a more sustainable urban development mode, including by recycling more waste (Figure 5.6, panel B). Educational Infrastructure Certificates and National School Infrastructure Bonds are funding improvements to education infrastructure.

Mexico City's New International Airport was designed to the highest standards of sustainability. Infrastructure to access the airport needs to be future-proof and the airport needs to be part of broader efforts to improve strategic regional transport planning and interjurisdictional integration in the Valle de México. The airport authority (GAMC) has enhanced its control and accountability processes, stepped up its code of conduct, and set up an ethics committee. Procurement has become more transparent. The government negotiated an air service agreement with the United States and increased the FDI share to 49% in regular and non-regular national air transport, non-regular international air transport and specialised air transport.

Despite these achievements, significant challenges remain. The corporate governance reform of GAMC needs to continue and a mechanism for a whole-of-government co-ordination around the New International Airport of Mexico City needs to be established. Procurement activities between different entities could be better co-ordinated and pre-tendering activities strengthened.

## **ORGANISATION FOR ECONOMIC CO-OPERATION AND DEVELOPMENT**

The OECD is a unique forum where governments work together to address the economic, social and environmental challenges of globalisation. The OECD is also at the forefront of efforts to understand and to help governments respond to new developments and concerns, such as corporate governance, the information economy and the challenges of an ageing population. The Organisation provides a setting where governments can compare policy experiences, seek answers to common problems, identify good practice and work to co-ordinate domestic and international policies.

The OECD member countries are: Australia, Austria, Belgium, Canada, Chile, the Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Israel, Italy, Japan, Korea, Latvia, Luxembourg, Mexico, the Netherlands, New Zealand, Norway, Poland, Portugal, the Slovak Republic, Slovenia, Spain, Sweden, Switzerland, Turkey, the United Kingdom and the United States. The European Union takes part in the work of the OECD.

OECD Publishing disseminates widely the results of the Organisation's statistics gathering and research on economic, social and environmental issues, as well as the conventions, guidelines and standards agreed by its members.

### **OECD “Better Policies” Series**

The Organisation for Economic Co-operation and Development (OECD) aims to promote better policies for better lives by providing a forum in which governments gather to share experiences and seek solutions to common problems. We work with our 35 members, key partners and over 100 countries to better understand what drives economic, social and environmental change in order to foster the well-being of people around the world. The OECD Better Policies Series provides an overview of the key challenges faced by individual countries and our main policy recommendations to address them. Drawing on the OECD's expertise in comparing country experiences and identifying best practices, the Better Policies Series tailor the OECD's policy advice to the specific and timely priorities of member and partner countries, focusing on how governments can make reform happen.

# Turning Pink Slips into Red Tape: The Unintended Effects of Employment Protection Legislation

Harlan Holt\*      Joshua R. Hendrickson†

January 26, 2015

## Abstract

This paper presents evidence on the link between employment protection legislation (EPL), such as mandated severance packages for fired workers, and the rate of unemployment in a cross-country panel data set of OECD countries from 1990-2013. We use both a traditional fixed effects panel specification with lags of the policy variable, and also a unique structural panel vector autoregression (PVAR) method to determine the long-run dynamic interaction between employment protection legislation and unemployment. We confirm that a tightening of EPL for permanently employed workers causes a significant and persistent increase in unemployment, but the effect is only apparent at long lag lengths, some 2-5 years after the law has been implemented. We find weaker evidence that employment protection legislation specific to temporary worker contracts also increases unemployment.

†University of Mississippi - Department of Economics, 229 North Hall, University, MS, 38677, jrhendr1@olemiss.edu

# 1 Introduction

Over the past five years, there has been a considerable effort on the part of many developed countries including Spain, Estonia, the UK, Italy and Portugal, to reduce the costs imposed on employers associated with hiring workers. While labor legislation debates typically revolve around the use of unemployment benefits and their distortionary effects on workers' labor-leisure allocation, relatively less attention is paid to the effects of Employment Protection Legislation (EPL), which is designed to protect the worker from losing his or her job by imposing additional costs on employers who fire their workers. These policies include state-mandated severance packages for firing workers, lengthy prior notice to terminated employees, and other administrative costs associated with dismissal.

The purpose of this paper is to determine whether the passage of additional EPL increases the rate of unemployment in a country, an effect that the prior literature has had difficulty confirming. To address this question, we present a fixed-effects panel model with lags of the policy variable and a panel vector autoregression (PVAR) specification which, to our knowledge, has not been used to address this question. The reason for the policy lag is that the choice of policy is not independent of the unemployment rate. Policy makers will base their legislative decisions in part on the current unemployment rate, thus any model that estimates the contemporaneous relationship between EPL and unemployment will have estimates that are biased and inconsistent due to simultaneity bias. The choice of policy however will be unrelated to the future unemployment rate because it is unobserved at the time the choice of policy is made. The policy lags also allow us to construct the basis for a long-run adjustment mechanism.

Even though we could conceivably identify a contemporaneous effect through the use of instrumental variables, focusing on the contemporaneous effect obscures much of the story. For example, consider the passage of an employment protection law. In the short run, it is improbable that firms would immediately begin firing workers because of the costs of immediately changing output decisions, in addition to the additional penalties resulting from firing workers under the new legislation. Thus in the short run, we should expect very little increase in unemployment, even if the effect is correctly identified. Instead, we expect that any interesting structural change in the unemployment rate will occur in the long run, and perhaps very far off into the future. This is because firms will much more likely wait for workers to leave their positions voluntarily, and then simply close the vacancy if they do not want to incur the cost of potentially firing the new worker. This means that previous research that focuses on the contemporaneous effect, underreports the

true impact on unemployment, *even if* the effect is correctly identified and estimated. In fact, if the effect is strong enough, we may even observe a temporary drop in the unemployment rate if businesses find it too costly to fire workers in the short run leading to an incorrect assessment of the policy's effects.

We believe this is a subtle point that deserves special emphasis. Many prior studies have found that increased employment protection have no effect on the unemployment rate (See: Addison and Grosso (1996), Nickell (1997), OECD (1999), Addison et al. (2000), and many others).<sup>1</sup> Our goal in this paper is not to refute or overturn prior studies that show that increased EPL has no effect on unemployment in the short-run. Rather, we heartily agree with these findings, and believe them to be very plausible. Our broader goal is to show that failure to investigate the long-run effects of this policy can lead to an incorrect policy recommendation. There are a number of reasons why the long-run effects may have escaped the prior literature. Foremost among them is that available data on EPL has only been available since the mid 1990's. Long-run investigation of policy requires a sufficiently large number of observations on the time dimension for the data to show the effects.<sup>2</sup>

We revisit the hypothesis that EPL increases unemployment, however we focus on the long-run impact of these types of policies.<sup>3</sup> We follow up the traditional panel model with a time series approach to identify the long-run adjustment path with a panel vector autoregression (PVAR). The use of the PVAR model is important for two reasons. First, the PVAR specification allows for the assumption that unemployment and EPL are endogenously related, but allows us to identify the causal effect without the problems of instrument selection. Second, we are able to use the PVAR model to compute the dynamic response of unemployment to a change in EPL rather than just the initial marginal effect. This allows us to observe how the unemployment rate evolves over time after an exogenous change in EPL.

In both the fixed effects panel model and the PVAR model, we find evidence that an increase in the degree of employment protection leads to significantly higher unemployment, but the effect is only apparent

---

<sup>1</sup>It is arguable that this is the general conclusion of the literature.

<sup>2</sup>A simple panel fixed-effects regression can estimate the impact of EPL on unemployment. However if we want to examine a long-run relationship on a data set with time dimension  $t = 1, \dots, T$  by including the policy variable from the year prior, we must cannot analyze the first and last time observations (the policy lag for year 0 is unobserved, and data in response to a policy change in year  $T - 1$  does not exist to be analyzed yet). Each subsequent lag we include in the regression consumes two additional degrees of freedom. Thus if you wished to examine the long-run effects of policy 4-5 years into the future, the researcher must throw away 8-10 years of observations. Because the EPL indices on OECD countries used by most studies on EPL only became available after Grubb and Wells (1993), this study in particular would not have been possible as recently as 5-10 years ago, much less 15-20 years ago when many of the referenced papers in this field were published.

<sup>3</sup>The impact on the unemployment rate in the long-run should not be confused with the long-run unemployment rate which is defined as the percentage of the labor force that has been unemployed for longer than one year. This study predominantly concerns the former, not the latter.

at long lag lengths, some 2-5 years after the adoption of new legislation. This implies that while these policies produce a persistently higher unemployment rate, the effects may not become apparent until well after the policy has been implemented, and potentially may even appear counter to the political cycle since many legislatures in developed countries are turned over only once every two to six years.

## 2 Employee Protection Legislation

### 2.1 The Effects of EPL on Unemployment

Historically the direct policy implementation of EPL across most developed countries has concerned the length and generosity of severance payments and the amount of notice or administrative effort required by firms to terminate the employment of a worker. While these are the two largest components of EPL, labor market rigidity produced through legal protections for collective bargaining as well as an array of other policies can also be interpreted as an employment protection law.

The implementation of EPL can be thought of as having a similar goal as unemployment insurance (UI), but targeted instead at those who have work rather than those who are out of work. To the extent that it allows workers to smooth consumption by reducing the uncertainty of their permanent income, it does function somewhat like UI or other types of unemployment benefits. However, as stated by Blanchard, Jaumotte, and Loungani (2013), the intended policy goals are somewhat different: "The purpose of *unemployment insurance* is to reduce the *pain* of unemployment. The purpose of *employment protection* is to reduce the *incidence* of unemployment."<sup>4</sup> Thus, in accordance with the stated policy goals, we can generate a direct testable hypothesis of whether or not EPL actually achieves its stated purpose of reducing the incidence of unemployment.

The desire to have the state enforce a level playing field between employers and employees has been historically popular in political circles, especially with regards to policies that do not bear an explicit pecuniary cost to the government. Pro-labor policies are often aimed at limiting the supposed advantages that a firm enjoys when bargaining over wages and employment status. For example, Section 1 of the U.S. National Labor Relations Act of 1935, which outlines the right for workers to organize, explicitly states that "The inequality of bargaining power between employees who do not possess full freedom of association or actual liberty of contract and employers who are organized in the corporate or other forms of ownership associa-

---

<sup>4</sup>Emphasis from the original authors.

tion substantially burdens and affects the flow of commerce . . . by depressing wage rates and the purchasing power of wage earners in industry.” Similarly, researchers have argued monopsony buying power of firms that arises from either specialization or switching costs provides the basis for pro-labor type policies such as the minimum wage and the right to unionize. The implementation of EPL has a similar political motive because these policies are intended to create better outcomes for laborers by making firms pay an extra cost to fire their workers. This paper takes no position on whether or not these employer advantages exist or to what degree they affect labor market freedom. However, we do wish to examine whether the use of legislative force to overcome these perceived disadvantages can actually lead to adverse outcomes for workers.

As stated, the intended goal of these policies is to reduce the incidence of unemployment. However, there is strong reason to believe that while EPL certainly does disincentivize the firm from firing or laying off its existing labor force, the policy may not work as intended. Increasing the cost to firing workers means that firms will likely be more reluctant to hire them in the first place. Since it doesn’t directly impact the firm’s productivity, it is unlikely that firms will react instantly to a tightening of EPL by firing workers. Instead they will likely be more inclined to simply close positions that workers leave voluntarily, leaving fewer positions for new workers to compete over. This means that the most important effects of the policy exist in the *long run*. The short run effect is ambiguous and perhaps not all that meaningful. Unemployment may rise, fall, or remain the same immediately after employment protection legislation is passed. Understanding this is crucial to correctly assessing the policy’s effectiveness. Econometrically, this means that any attempt to estimate the effect of employment protection laws on unemployment must necessarily focus on the long run effect of the policy, including examining the dynamic adjustment path from one level of unemployment to the next.

This logic is consistent with labor market search models, such as that of Pissarides (2000), which imply that increases in the ex ante cost of hiring workers leads to an increase in the unemployment rate and a reduction in the vacancy rate in the steady state. In addition, EPL might increase unemployment if it impedes labor market reallocation as others such as Bertola and Boeri (2002) have suggested. Thus, in the long run, we expect to see fewer vacancies and a higher unemployment rate directly contradicting the stated purpose of the law.

Since the number of vacancies is expected to fall, we should expect the additional unemployment generated by these policies to be persistent. That is, we do not expect to see a spike of unemployment which gradually returns to the steady state as we might with an ordinary aggregate demand or supply shock. Thus,

the type of unemployment created by these incentives is likely to be structural and long-term in nature.

## 2.2 Recent Work

Lazear (1990) uses a panel model of 20 developed nations with a quadratic time trend to show that increases in mandatory severance packages to terminated employees have a positive effect on the unemployment rate, and a negative effect on the employment-to-population ratio, the labor force participation rate, and average hours worked. Lazear also estimates the regression with country fixed effects, and is able to confirm his results for all of the dependent variables *with the exception of* the unemployment rate. Lazear justifies this by stating that if employment protection causes structural unemployment, then over the long run we would expect more discouraged workers and the unemployment rate might indeed *fall*. This, however is unlikely given that his panel results reflect the instantaneous change in unemployment due to an increase in severance pay, whereas a discouraged worker problem is likely only to arise after a considerable time has passed.

Lazear (1990), and most of the accompanying literature says little about how long it can take for the effects of changes in the structure of employee protection legislation to appear in the aggregate employment statistics for an economy. Most studies focus on the contemporaneous impact of employment protection legislation on unemployment. The results have generally suggested that EPL has little to no effect on the unemployment rate. For instance, Addison and Grosso (1996), Nickell (1997), OECD (1999), Addison et al. (2000), Nickell et al. (2005), Sarkar (2013), and Avgadic (2013) all fail to find evidence that the unemployment rate is increased after additional employment protection is legislated. In addition to Lazear (1990), Scarpetta (1996), and Heckman and Páges (2000, 2003), find evidence of an increase in unemployment after an increase in the degree of employment protection.<sup>5</sup>

A more uncontroversial finding from the literature is that flows into and out of unemployment fall, suggesting that unemployment becomes more stagnant as a result of stricter EPL.<sup>6</sup> Once again, this is not surprising given the likely transmission mechanism as described above. If businesses do not immediately react to additional EPL by firing workers, but by reducing the amount of vacancies they post in the future, then this is consistent with both a small, nonexistent, or possibly even negative short run effect of EPL on unemployment and reduced employment flows.

<sup>5</sup>For an excellent survey of the literature, see Addison and Teixeira (2003).

<sup>6</sup>For examples, see OECD (1999), Kugler and St. Paul (2000), and Autor et al. (2007).

### 2.2.1 Estimation Issues

Despite the considerable depth of the literature, there is really no careful identification of the long-run trend of employment after a change in EPL. This is likely because of the availability of the data. Reliable EPL indicators as explored by Grubb and Wells (1993) have only been established since Lazear's (1990) seminal work. The most widely used data set, the OECD's EPL indicators, only report data back to 1990 for most nations, which means we have less than 25 years of data for this particular measure. It is relatively easy to establish contemporaneous effects in a panel model, however when trying to identify the long-run effect, the researcher inevitably consumes degrees of freedom quickly. What's more, as Nickell (1981) shows, dynamic panel models which attempt to incorporate a partial adjustment mechanism such as an AR(1) process for unemployment, like those suggested by Arellano and Bond (1991), can produce biased estimates in samples with a relatively small time dimension. It is no coincidence then that most of the previous studies on this topic do not even attempt to identify the long run marginal effects of EPL on unemployment, instead focusing on the contemporaneous impact of those laws. Sarkar (2013) summarizes the need for more long-run tests by stating, "A panel regression based on a short-term time series has the constraint of studying only the instantaneous relationship, which may not be meaningful; rather it may be spurious."

The focus on the contemporaneous effect of EPL is potentially problematic from an empirical perspective since the unemployment rate and EPL might be simultaneously determined. Many examples indicate why simultaneity might be a problem. Politicians may choose EPL to combat spells of high or rising unemployment. It is also possible that implementation lags may cause the policy to actually be enacted after the recessionary spell has passed leading to a spurious correlation between low or falling unemployment and EPL. On the contrary, since EPL policies represent a form of unemployment insurance for currently employed workers, it may be that EPL policies have greater political support when unemployment is low or falling as the economy exits a recession. If we wish to investigate how EPL affects unemployment, we must take into account the fact that unemployment almost certainly affects EPL as well.

In addition, even if these problems are corrected for the contemporaneous relationship between EPL and unemployment, there may still be reason to be skeptical about the policy implications of not finding a statistically significant relationship. This is because the long run *structural* relationship between EPL and unemployment may be very different than the instantaneous one. This would very likely be the case if the transmission mechanism described above is indeed the case. If employers react to a sudden tightening of

EPL not by immediately firing workers, but by closing future vacancies, then we should very likely see the detrimental effects of the policy only in the future, not in the immediate aftermath of the policy.

A recent attempt to reconcile these issues is Sarkar (2013), who uses an error correction panel model to examine the effects of EPL on unemployment. Sarkar fails to find a long run relationship between general unemployment and EPL, though he does find evidence that additional EPL can increase the proportion of the long-term unemployed population, which can reduce production which then further aggravates long-term unemployment.<sup>7</sup> Nonetheless, there is reason for skepticism about these results. First, Sarkar's model requires that the variables are non-stationary. In samples with a small number of observations across time, however, unit root tests are likely to over-accept the hypothesis of a unit root. Examination of the autocorrelation functions (ACFs) of the variables used in this paper cast doubt on the presence of non-stationarity. In Figure 1 we plot the ACFs for the G-7 countries plus Australia for the sample period 1990-2013. Visual inspection of the plots show that the autocorrelation of unemployment is statistically greater than zero for no more than a two year lag. Thus, we find the hypothesis of a unit root in unemployment doubtful. Second, Sarkar's failure to find a long-run relationship between EPL and unemployment is based on an absence of evidence of cointegration between the two variables. However, Sarkar finds evidence that EPL is cointegrated with GDP. Thus, the relevant test within the context of a vector error correction framework when there is cointegration is to test the hypothesis that the coefficient on EPL is equal to zero in the cointegrating vector rather than test for bivariate cointegration.

Whatever the mechanism, it is clear that the choice of EPL is partly determined by the present unemployment rate, thus any estimates of a contemporaneous effect of EPL on unemployment that do not take this into account are likely to be biased and invalid for policy inference. We address this in two ways. First, we use a fixed effects model to examine the effect of EPL on unemployment using various policy lags for employment protection. Second, we use a panel vector autoregression (PVAR) model to examine the effect of EPL on unemployment. Given the possibility of endogeneity, this second approach is important because tools like vector autoregression models treat all variables as endogenous. To our knowledge we are the first authors to pursue this latter approach.

---

<sup>7</sup>Long-term unemployment here refers to the percentage of the labor force unemployed for longer than a year, not the long-run trend of unemployment.

### 3 Data

We measure the degree of employment protection using indexes of employment protection for permanent workers and for temporary workers constructed by the OECD. The OECD's EPL measures are compiled using 21 different individual indicators on mandatory severance packages and administrative costs of dismissal tiered by employee tenure and the pervasiveness of unions and collective bargaining at the industry and national level. The OECD organizes these measures separately for permanent and temporary workers. The data spans the 34 OECD member countries over the period from 1990 to 2012. Summary statistics for these variables and the unemployment rates by country are provided in Table 1. Each indicator is assigned a score from 0 to 6 based on answers from a questionnaire on the strictness of the labor code with regards to that particular indicator with 0 being the least strict, and 6 being the most. Each item in the survey is then assigned a weight and then added up into component scores for procedural inconveniences, length of notice and severance pay, difficulty of dismissal, and additional provisions for collective dismissal. These component scores are again weighted and then combined into a final employment protection score from 0-6.<sup>8</sup>

Shortly after Lazear (1990), the need for better measures of employee protection became apparent. Grubb and Wells (1993) suggested that new measures incorporate not only the level of mandatory severance packages, but the length of term of prior notice needed to be given to individuals, tiered measures for the level of tenure among employees, and the differences arising from permanent versus temporary work positions. The modern measures of employee protection are largely based on the Grubb and Wells methodology.

The remaining variables in our model are taken from the World Bank's World Development Indicators. These variables include the unemployment rate, the percentage of unemployed who are identified as long-term unemployed (over one year), government expenditures as a percentage of GDP, inflation as determined by the CPI for each country, and income per capita growth defined as the log difference of real per capita income in constant 2005 US dollars to serve as control variables. A brief summary of these data is presented in Table 2.

---

<sup>8</sup>Since the scores for each category are weighted, and then aggregated, the final EPL measure assigned to each nation is not, in general, an integer value. This is beneficial in terms of the data since it increases the variation of EPL for the sample along both the cross sectional and time dimensions.

## 4 Fixed Effects Model

### 4.1 Model Specification

To examine the relationship between employment protection and unemployment, we begin with the following fixed effects model:

$$unemp_{i,t} = \beta_1 Perm_{i,t-k} + \beta_2 Temp_{i,t-k} + \beta'_X \mathbf{X}_{i,t} + a_i + a_t + u_{i,t} \quad (1)$$

where *unemp* is the unemployment rate in country *i* in year *t*, *Perm* is the value of the strictness of employment protection indicator for permanent work positions, and *Temp* is the value of the strictness of employment protection for temporary positions.  $\mathbf{X}_{i,t}$  is a vector of basic control variables for unemployment in which we include the inflation rate to control for Phillips' curve effects, the growth rate of real per-capita GDP to control for Okun's law, and real government expenditures. We also include year fixed effects,  $a_t$ , to control for any global factors such as the global financial crisis that began in 2008.<sup>9</sup>

The choice of the fixed effects model is due to the fact that unobserved heterogeneity between countries is likely correlated with the explanatory variables. For example, Venn (2009) finds that EPL is correlated with the countries' legal origins. EPL is also likely to be correlated with other factors, many of which will be unobservable concerning the connection between labor market structure and the legal environment in which it operates. Examples might include the favorability of judgements in labor proceedings by the country's judicial system, the degree of monopoly or monopsony power of firms in key industries, or other effects produced by unrelated and unobserved government policies.

### 4.2 Results

A drawback of any specification of this type is that the contemporaneous effect of the EPL measure will be determined simultaneously with the unemployment rate. This is because lawmakers may find it more difficult to pass EPL during periods of high unemployment or may be more determined to do so while the unemployment rate is low. Any estimate of the contemporaneous effect of EPL on employment will be endogenously determined by reverse causality and will be unsuitable for policy analysis. Because of the high degree of serial correlation with unemployment rates, it is doubtful that even the first or second lags

---

<sup>9</sup>We also tested a specification with time trend instead of time dummies. The results were not significantly affected.

escape this endogeneity problem since the unemployment rate strongly depends on its previous value.

While the potential for simultaneity bias prevents us from saying anything about the instantaneous effect of the policy change, we can determine the long run effects of the policy by using lags of the policy since the future unemployment rate should not affect any policy change in the present. We use single, discrete lags of the policy variable for each regression, not a distributed lag. The choice of a single lag rather than a distributed lag is because the changes in EPL for each country are generally infrequent, at most occurring once every 5-10 years and sometimes not at all. Legislative overhauls of most sensitive national policy positions such as labor law often take considerable political effort, and the majority of votes needed to do so only occurs every so-often. Because of this, inclusion of a distributed lag of the policy variable is improper, because we would likely be introducing multicollinearity among the regressors which would reduce the precision of our coefficient estimates. We present the estimates of the specification using differing lag lengths of the policy variables in Table 3.<sup>10</sup>

As shown in Table 3, the EPL measure for permanent workers has a positive and statistically significant for lags of 2 - 5 years. The contemporaneous EPL measure for temporary workers is negative and statistically significant. However, we suspect that this is due to the potential for simultaneity bias. At the bottom of Table 3 we include the Akaike and Schwarz-Bayes Information Criteria (AIC and SBC) . The information criteria both uniformly decline as the lag gets longer indicating that the model fits better the further out from the policy change we get.

It is reasonable to suppose that if labor market rigidity were tightened through increases in EPL, we should also expect more of the workforce to become structurally unemployed as a result. This is because EPL may have uniform effects that differ across industries. For instance, we would likely expect firms that operate in industries that experience historically high turnover rates such as dining or retail to be affected more than historically low turnover industries such as finance. In this case, we would expect the workers displaced by this policy to have more difficulty finding suitable employment elsewhere, implying structural employment should rise. This type of unemployment is generally more painful for an economy because it tends to be persistent and longer lasting than other types. We use long-term unemployment as a proxy since direct measures of structural unemployment are not widely available. Using the same specification as equation (1), we present the results using long-term unemployment as a percentage total unemployment as

---

<sup>10</sup>We also estimated equation (1) with a regional fixed effect to control for regional supply shocks such as a natural disaster, changes in regional trading patterns, or localized systemically important asset market conditions. We also included regionally clustered standard errors. These changes did not significantly alter the regression results.

the dependent variable. The results are presented in Table 4.

As shown in Table 4, the measure of employment protection for permanent workers is positive and statistically significant for both the model with a four year policy lag and the model with a five year policy lag. The long time lags should not be surprising. Structural unemployment takes time to appear in the data since it is, by nature, a long-term phenomenon. The increase in structural unemployment is problematic for governments. Structural unemployment is generally stubborn and can take time to dissipate, leading to more pressure over time on social safety nets to provide for the unemployed and the loss of taxable income from the newly created structurally unemployed.

## 5 Panel Vector Autoregression Model

In this section we provide evidence of the effect of employment protection on the unemployment rate using an estimation method that has not previously been used in the literature. Specifically, we use a panel vector autoregression (PVAR) specification similar to Holtz-Eakin, et al. (1988) to capture the long run effects of changes in EPL on the unemployment rate by focusing on the long run dynamic transmission of the policy impact on unemployment. The PVAR model has two key advantages. First, it allows us to preserve the effects of unobserved heterogeneity between countries while assuming that the variables are endogenous. Second, the PVAR allows us to recover the orthogonal policy innovations at the cost of imposing a sufficient number of identification restrictions on the data. We use the recovered policy innovations to plot the dynamic response path of the unemployment rate to a change in either of the EPL policy variables with an impulse response function (IRF). Intuitively, once the model is appropriately identified, the IRFs plot the dynamic path of the unemployment rate in response to an unexpected increase in EPL.

The PVAR model is given as

$$AY_{i,t} = B_0 + B_1Y_{i,t-1} + a_i + \varepsilon_{i,t} \quad (2)$$

where  $Y_{i,t}$  is a vector of endogenous variables,  $a_i$  are country fixed effects included to account for any non-time varying, unobserved heterogeneity among the countries,  $A$ ,  $B_0$ , and  $B_1$  are coefficient matrices, and  $\varepsilon_{i,t}$  is a vector of structural shocks.<sup>11</sup> Here, the term structural shock refers to an unanticipated change in a

<sup>11</sup>To estimate the regression equation in (2), we first need to transform the variables to remove the fixed effects by applying a Forward Orthogonal Difference (FOD) procedure as in Arellano and Bover (1995), also commonly known as a Helmert transformation. We then estimate a reduced form representation of (2) and use a Choleski decomposition to uniquely identify the structural shocks of the system. For those unfamiliar with VAR methods, the econometric details on the transformation and estimation procedure are

particular variable.

The vector,  $Y$ , includes the endogenous policy variables  $Perm$  and  $Temp$  from the panel regression earlier and the unemployment rate. It is important to note that equation (2) cannot be estimated directly because the model implies that  $Y_{i,t}$  is correlated with  $\epsilon_{i,t}$ , which violates standard estimation assumptions. As a result, we first have to estimate a reduced form representation of (2). After the reduced form estimation, we can recover the structural shocks by imposing a sufficient number of identifying restrictions on the matrix  $A$  in equation (2), which captures the contemporaneous relationships between the variables.

We use a Choleski decomposition to identify the model, which amounts to forcing  $A$  to be lower triangular with zero entries below the principle diagonal, and free parameters elsewhere. Intuitively, the Choleski decomposition is consistent with the assumption that the variables in  $Y_{i,t}$  have no contemporaneous effects on the variables ordered above them. This carries the potential drawback that the ordering of the variables in the regression equation matters for the estimates because the identifying assumptions change. As is common in the estimation of multiple time series using a Choleski decomposition, we test the model using different orderings of the variables to show that the estimates are robust to the identifying assumptions. The first identification strategy orders the unemployment rate first and the policy variables last. This is consistent with the assumption that the policy variables do not have a contemporaneous effect on unemployment. The second identification strategy order the policy variables first and the unemployment rate last. This is consistent with the assumption that the policy variables do have a contemporaneous effect on unemployment. Once we have recovered the structural shocks, we can then plot impulse response functions that capture the dynamic response of the unemployment rate to unanticipated changes in the measure of EPL.

The path of the unemployment rate in response to a shock to employment protection for permanent workers is shown by the impulse response function in Figure 2. The number of years after the shock is plotted on the horizontal axis and the magnitude of the response of unemployment is plotted on the vertical axis. The solid line plots the estimated response of unemployment and the dotted lines represent the 95% confidence interval calculated from bootstrap simulations of the model. As shown in Figure 2, a change in employment protection for permanent workers leads to a positive and statistically significant change in the unemployment rate for each of the five periods following the shock. In addition, the estimates imply that the unemployment rate continues to rise for five years after the policy change. The estimates imply that a one point increase in employment protection (e.g. an increase from 0 to 1 in the EPL statistic) would result in a

---

located in Appendix A.

0.16 percentage point increase in the unemployment rate after five years.

To put this effect in the context of policy choice consider the comparison of the United States and Sweden. In the sample used in this paper, the average unemployment rate in Sweden was 6.97% whereas the average unemployment rate for the U.S. was 5.97%. The average value of the index of employment protection legislation for Sweden over the sample was 2.68 where the average value of the index was 0.26 for the U.S. Our estimates imply that the difference in employment protection legislation can explain 38.7% of the difference in unemployment between Sweden and the U.S.

Similar results are shown in Table 5 for the G7 countries. The second column in Table 5 lists the difference in the average unemployment rate over the sample period for the country listed and the United States. The last column of Table 5 shows the fraction of the difference in unemployment that can be explained by differences in employment protection legislation, given our estimates. As shown, five of the six remaining G7 countries had higher unemployment rates than the United States over the sample period. Our estimates suggest that the difference in the degree of employment protection can explain 8.4% to 17% of the difference in unemployment for these five countries, or 12.94% on average.

The path of the unemployment rate in response to a shock to employment protection for temporary workers is shown in Figure 3. The estimates in this figure assume that policy has no contemporaneous effect on unemployment. As shown, employment protection for temporary workers has a positive effect on the unemployment rate for each of the five periods after the shock. However, the change is not statistically significant.

Figures 4 and 5 plot the estimated path of the unemployment rate following a shock to employment protection for permanent and temporary workers, respectively, under the assumption that policy has a contemporaneous impact on unemployment. As shown in Figure 4, the initial effect is negative, but not statistically different from zero. Nevertheless, the effect of employment protection on the unemployment rate is positive and statistically different from zero beginning three years after the shock and the point estimates are of a similar magnitude as shown in Figure 2. This is also identical to the pattern found in our original simple panel estimates in which policy lags of 3 years or more showed a positive and statistically significant effect on unemployment. This also shows that the earlier results are robust to alternative causal ordering of the vector of endogenous variables since the effect of EPL on unemployment remains positive despite different assumptions about the contemporaneous effects. Figure 5, however, shows that the effect of employment protection for temporary workers on the unemployment rate is not statistically different from zero for any

period after the shock.

These results imply that EPL for permanent workers has a positive and statistically significant effect on unemployment. As hypothesized in the introduction, this effect tends to appear with a lag. Thus, policymakers and researchers should be concerned with the impact that EPL has on the unemployment rate far into the future, and should not just with the immediate impact of the legislation.

## 6 Conclusion

Employment protection legislation is used in a number of countries to specify the length and generosity of severance packages as well as the legally required amount of advanced notice and administrative costs associated with the termination of workers. For politicians these policies are appealing because they purport to reduce unemployment without a direct, explicit cost to the government. Our paper examines the impact of additional EPL on unemployment and tells a much different story. The initial effect of additional employee protection on unemployment is low or even negative. This may give policymakers the false impression that these policies can be enacted to protect workers from being fired without imposing additional costs on society. However, our results indicate that an increase in EPL does increase unemployment in the long run, and may not even be noticeable until after several years have passed. Presumably, this is because employers do not immediately fire workers after additional EPL is enacted, but close vacant positions opened up by workers who leave voluntarily. This finding potentially reconciles the two arguments in the literature that additional EPL does not immediately increase unemployment, but does reduce employment flows by making pools of unemployed more stagnant.

While the policy does not cost the state anything explicitly, the societal costs of maintaining a persistently larger population of unemployed are potentially quite large. Thus, the policy recommendation outlined by this paper is that OECD governments would be wise to lower the mandated costs associated with firing workers in order to permanently reduce the level of unemployment. In light of our findings, the efforts of nations in the EU to reduce EPL as part of their labor market reforms are likely to encourage labor market health in those countries over the next five years.

## Appendix A: PVAR Estimation Details

The Panel VAR is shown in equation (2) as

$$AY_{i,t} = B_0 + B_1Y_{i,t-1} + a_i + \varepsilon_{i,t}$$

Direct estimation of this equation is not possible for two reasons. First, the country-specific fixed effect,  $a_i$ , is correlated with the lagged dependent variables, so any estimated coefficients would be biased (but not inconsistent), as demonstrated by Nickell (1981). To eliminate this fixed effect from the regression, we use the Forward Orthogonal Difference (FOD) technique proposed by Arellano and Bover (1995), also commonly referred to as the Helmert transformation. This procedure transforms each of the variables into deviations from the means of all of the future instances of that variable. This removes the fixed effect, but does not produce a correlation between the transformed variables and the error term, and Nickell bias is no longer problematic.

Let the forward mean of any single variable in  $Y$  be given by

$$\bar{y}_{i,t} = \sum_{t+1}^T \frac{y_{i,t+1}}{(T-t)} \quad (3)$$

The transformed variables are then,

$$\tilde{y}_{i,t} = c_{i,t}(y_{i,t} - \bar{y}_{i,t}) \quad (4)$$

where  $c_{i,t} = \sqrt{(T-t)/(T-t+1)}$  is a constant included to equalize the variances.<sup>12</sup> Denote the vector of transformed variables as  $\tilde{Y}_{i,t}$ . The transformed structural VAR can be written as

$$A\tilde{Y}_{i,t} = B_0 + B_1\tilde{Y}_{i,t-1} + \tilde{\varepsilon}_{i,t} \quad (5)$$

Second, the model cannot be estimated in this form since it implies that all of the variables in  $Y_{it}$  have contemporaneous effects on the others. Thus, to estimate the equation above, we need to re-write the VAR as

$$\tilde{Y}_{i,t} = \Gamma_0 + \Gamma_1\tilde{Y}_{i,t-1} + e_{i,t} \quad (6)$$

---

<sup>12</sup>For details, see Arellano and Bover (1995).

where  $\Gamma_0 = A^{-1}B_0$ ,  $\Gamma_1 = A^{-1}B_1$  and  $e_{i,t} = A^{-1}\tilde{\epsilon}_{i,t}$ .

It should be noted that (6) is a reduced form equation. It can be estimated by applying equation-by-equation OLS. The resulting  $e_{i,t}$ 's, however, are not orthogonal. To identify the structural shocks,  $\tilde{\epsilon}_{i,t}$ , we must make assumptions about the structural model in (5) by placing restrictions on the matrix  $A$ . As is common in analysis of multiple time series, we use a Choleski decomposition, which forces  $A$  to be lower triangular with zero entries below the principal diagonal. This amounts to assuming that the variable ordered first in  $\tilde{Y}$  is not contemporaneously affected by the variables ordered below it. The Choleski decomposition is popular with multiple time series analysis because it guarantees enough restrictions to just identify the structural shocks, so under or over-identification is not an issue. As is common in this literature, we provide a robustness check by re-ordering the variables in the VAR to show that the results are not sensitive to ordering of the variables.

Just identification through the Choleski decomposition ensures that we can recover the  $\tilde{\epsilon}_{i,t}$  from the data. This allows us to generate causal inference. Transforming (6) into the moving average representation and substituting for  $e_{i,t}$  yields

$$\tilde{Y}_{i,t} = \tilde{Y} + \sum_{j=0}^{\infty} \Gamma_1^j A^{-1} \tilde{\epsilon}_{i,t-j}, \quad (7)$$

The impulse response is therefore given as

$$\frac{\partial \tilde{Y}_{i,t}}{\partial \tilde{\epsilon}_{i,t-j}} = \Gamma_1^j A^{-1}$$

These impulse responses represent the marginal effect of a shock to  $\epsilon_{i,t-j}$  on the variables contained in  $\tilde{Y}_{i,t}$  at time  $t - j$ . By collecting and plotting the impulse responses for  $j = 0, 1, 2, \dots$  we can observe the dynamic response of a variable in  $\tilde{Y}_{i,t}$  to an orthogonal innovation in  $\tilde{\epsilon}_{i,t-j}$ .

Countries	34		
Observations	651		

Time means and standard deviations for the unemployment and strictness of protection index measures for the 34 countries in the sample. Data covers 23 years from 1990 to 2012. Data for unemployment is collected from the World Bank's World Development Indicators. The strictness of protection measures are obtained from the OECD. The data comes after German reunification in 1990, so we do not need special treatment for Germany.

Table 2: Summary statistics for control variables

	Mean	Standard Deviation	Max	Min
Government expenditures as a percentage of GDP	19.20	4.16	26.89	10.79
Inflation	5.94	8.03	44.72	-0.52
Income per capita growth rate	1.71	1.00	5.05	0.47

Table 5: Unemployment Differences and Employment Protection – G-7

Country	Difference in Avg. Unemployment	Fraction Explained by EPL
Canada	2.25	11.0%
France	4.02	8.5%
Germany	2.35	16.9%
Italy	3.49	11.4%
Japan	-2.03	–
United Kingdom	0.81	17.0%
Average		12.94%

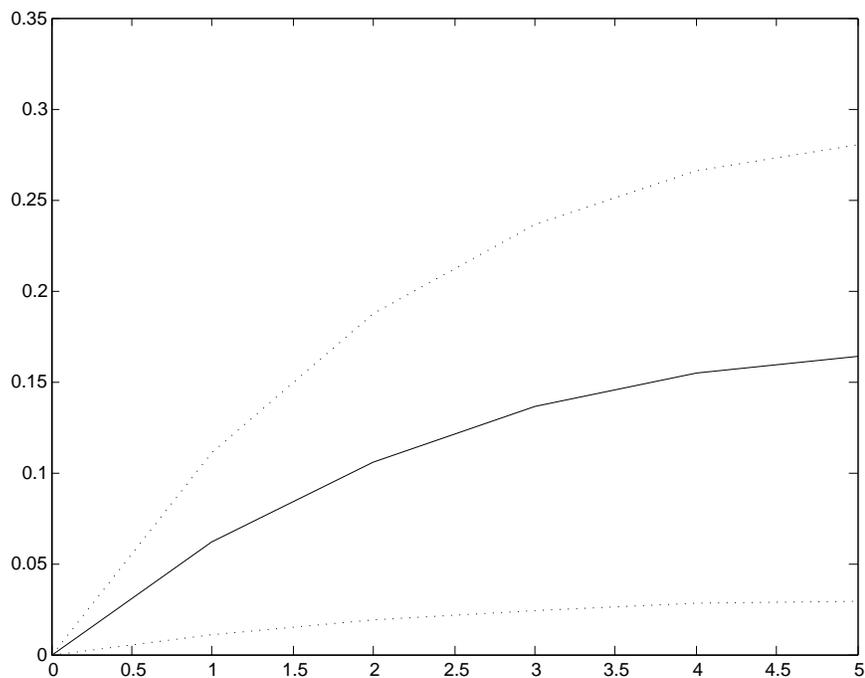

Figure 2: **Response of the Unemployment Rate to a One Unit Shock in Employment Protection for Permanent Workers (No Contemporaneous Policy Effects).** This figure shows the response of the unemployment rate (vertical axis) to an unanticipated increase in employment protection legislation of one point for permanent workers over time (horizontal axis) in years. This estimate assumes that changes in employment protection legislation have no contemporaneous effect on unemployment. The solid line shows the estimated response. The dotted lines represent the 95% confidence interval.

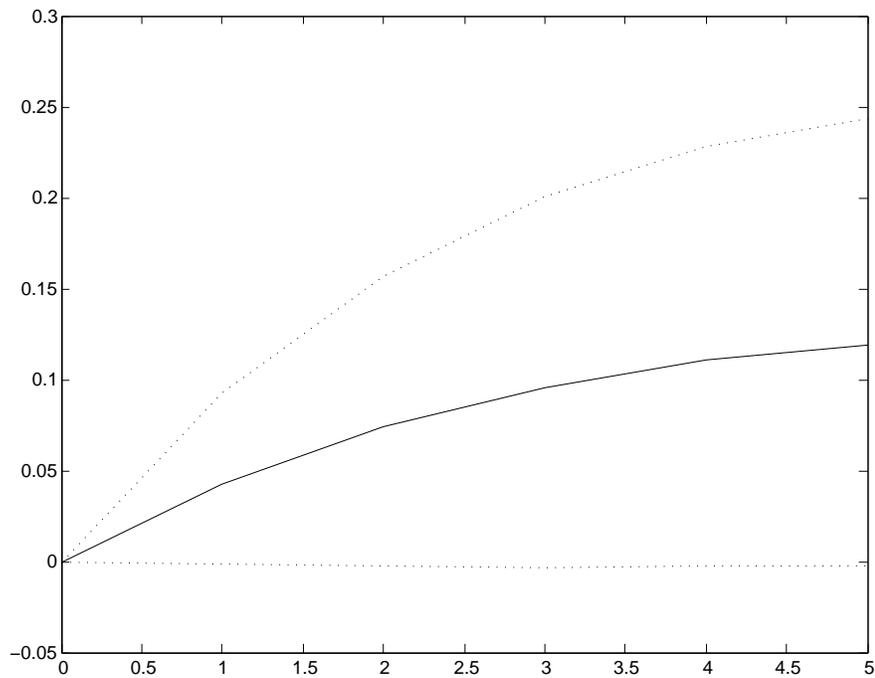

Figure 3: **Response of the Unemployment Rate to a One Unit Shock in Employment Protection for Temporary Workers (No Contemporaneous Policy Effects)**. This figure shows the response of the unemployment rate (vertical axis) to an unanticipated increase in employment protection legislation of one point for temporary workers over time (horizontal axis) in years. This estimate assumes that changes in employment protection legislation have no contemporaneous effect on unemployment. The solid line shows the estimated response. The dotted lines represent the 95% confidence interval.

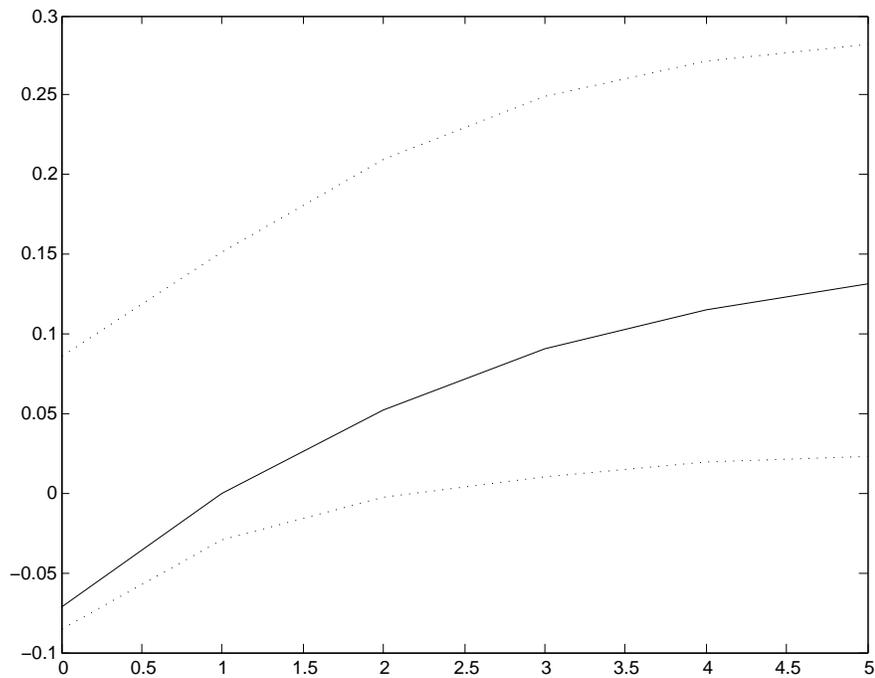

Figure 4: **Response of the Unemployment Rate to a One Unit Shock in Employment Protection for Permanent Workers (Contemporaneous Policy Effects)**. This figure shows the response of the unemployment rate (vertical axis) to an unanticipated increase in employment protection legislation of one point for permanent workers over time (horizontal axis) in years. This estimate assumes that changes in employment protection legislation has a contemporaneous effect on unemployment. The solid line shows the estimated response. The dotted lines represent the 95% confidence interval.

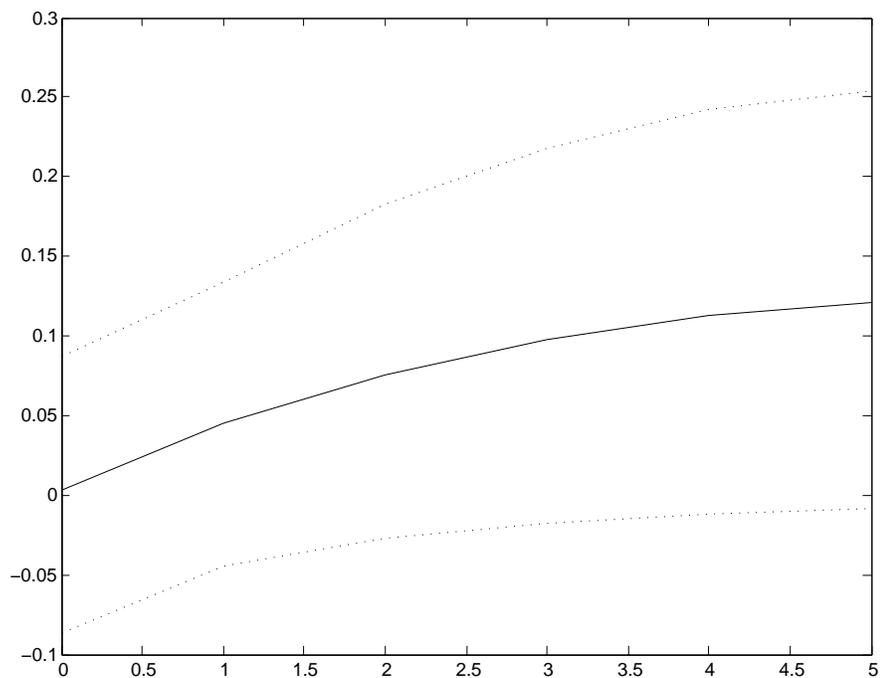

Figure 5: **Response of the Unemployment Rate to a One Unit Shock in Employment Protection for Temporary Workers (Contemporaneous Policy Effects)**. This figure shows the response of the unemployment rate (vertical axis) to an unanticipated increase in employment protection legislation of one point for temporary workers over time (horizontal axis) in years. This estimate assumes that changes in employment protection legislation has a contemporaneous effect on unemployment. The solid line shows the estimated response. The dotted lines represent the 95% confidence interval.

# Unemployment and Labor Market Rigidities: Europe versus North America

Stephen Nickell

**H**ere is the received wisdom. The European job market is rigid and inflexible. Result: high unemployment. The North American job market is dynamic and flexible. Result: low unemployment. So Europeans had better do something about their labor markets unless they want permanent double digit unemployment.

In fact, this is not *totally* wrong. There are features of the labor markets in some European countries that help sustain high levels of unemployment. Some of these features can be thought of as rigidities. However, there are many other so-called rigidities that do not cause high unemployment and, indeed, may serve a useful purpose. So it is important to know which features of the labor market cause high unemployment and which do not. This is the subject of what follows.

## Labor Market Outcomes in Europe and North America

While it is sometimes convenient to lump all the countries of western Europe together in order to provide a suitable contrast to North America, most of the time it is a rather silly thing to do. Different European countries are effectively different labor markets with the intercountry movement of labor being very small, mainly because of language and cultural barriers. Partly as a consequence of these differences, labor markets in Europe exhibit enormous diversity; in fact, differences within Europe are much greater than are the difference between the European average and North America. This section looks at some of these differences, first

■ *Stephen Nickell is Professor of Economics, Institute of Economics and Statistics, University of Oxford, Oxford, United Kingdom.*

with regard to unemployment and then with regard to other labor market outcomes, notably job and worker mobility, and wage flexibility.

Table 1 sets out some information on unemployment<sup>1</sup> where we focus on the recent past, namely the period following the major recession of the early 1980s. The first column provides an up-to-date summary picture; the other columns present averages over two subperiods, which will be used for more detailed analysis. The immediate point that stands out is the enormous variation in European rates. Taking the period 1983–1996, these stretch from 1.8 percent in Switzerland to 19.7 percent in Spain. This variation means that around 30 percent of the popu-

<sup>1</sup> Table 1 uses OECD standardized rates, with the exception of Austria, Denmark and Italy. For Austria and Denmark, the table presents national registered rates. For Italy, the table presents the unemployment rate as calculated by the U.S. Bureau of Labor Statistics “on U.S. concepts.” Aside from Italy, the OECD rates and BLS rates are very similar. For Italy, the OECD rates appear to include the large number of Italians who are registered as unemployed but have performed no active job search in the previous four weeks. Finally, the unemployment rate here is for *West* Germany, both to maintain comparability across time and because including a “transition economy” in the data would weaken comparability across countries.

lation of OECD Europe lives in countries and operates in labor markets with average unemployment rates lower than that of the United States.

A closer look at Table 1 raises two additional points. First, the European countries with the lowest unemployment rates (Austria, West Germany, Norway, Portugal, Sweden and Switzerland) are not noted for the flexibility of their labor markets. Britain, on the other hand, has always had the most flexible labor market in Europe on standard measures and yet has an average unemployment rate higher than half of its European neighbors.

Second, it is worth remarking on the fact that the variation in short-term unemployment is substantially smaller than that in long-term unemployment, where long-term is defined as a duration of more than a year. Thus, while countries require some short-term unemployment, long-term unemployment appears to be an optional extra. The reason is that long-term unemployment, in contrast to the short-term variety, contributes very little to holding down wage pressure and hence inflation (OECD, 1993, p. 94). The long-term unemployed are far enough away from the active labor market that their presence has little influence on wages. So if some suitable microeconomic policy can eliminate long-term unemployment, this will have few adverse macroeconomic implications. That is, it will not require much of a rise in short-term unemployment to maintain stable inflation.

Instead of concentrating on unemployment rates, some commentators prefer to focus on total employment, noting, for example, that North American employment has risen much faster in recent years than has European employment. Such a contrast is not helpful, however, because there is no control for different rates of growth in the population of working age. Controlling for this by normalizing on the size of the labor force takes one back to unemployment. A more reasonable alternative is to focus on employment/population ratios, although these tend to be strongly influenced by all the social and cultural factors that affect the labor market participation of married women. Table 2 presents evidence on alternative labor supply measures, like the employment/population ratio.

The first two columns of Table 2 show the ratio of employed persons to the total working-age population and the ratio for males ages 25–54. The cross-country variation in overall employment/population ratios is due to a variety of factors. Particularly important are variations in the participation rates of married women (which are very low in southern Europe), variations in the retirement rates of those over the age of 55 (OECD, 1996, p. 188) and variations in the employment rates of prime-age men, shown in the second column of the table. The third column of the table shows annual hours worked by the average worker in these different economies. Differences in this column are dominated by the extent of part-time working and by variations in weekly hours and annual holiday entitlements. Many countries in continental Europe have low annual hours actually worked even excluding part-time workers, because of their low weekly hours and long annual holidays compared to those of the United States and Japan. This does not imply that European workers would like to work more paid hours per year. Indeed, across the EC, more people would like to work *fewer* paid hours than would like to work more paid hours at

given hourly rates (European Economy, 1995, Table 25a). The final column, “overall labor supply,” combines the annual hours worked and employment/population ratios. Take the annual hours worked as a percentage of 2080 hours, which represents a full-time year of working 40 hours a week for 52 weeks. Multiply this by the employment/population ratio. The result can be thought of as the proportion of total “potential” hours worked in the economy. Total labor supply varies enormously across countries, with Japan, Portugal and the United States all supplying about two-thirds of potential hours, while Spain and Belgium supply barely 40 percent of potential.<sup>2</sup>

Another way of putting the unemployment/rigidity story into a broader perspective is to look at job and worker mobility. Job turnover is defined as the sum of the gross job creation and job destruction rates across companies; that is, the total of all new jobs generated plus all old jobs destroyed. Worker mobility includes

<sup>2</sup> Of course, these numbers exclude unmeasured labor input into, for example, the “black economy.” However, these total labor supply numbers are worth bearing in mind when comparing GDP per capita across countries.

all job turnover, but also includes the numerous occasions where workers enter or leave a job in a company when the overall number of jobs remains fixed, because of quits, retirements and so on. Of course, there are problems of comparability with cross-national data such as these (Contini et al., 1995), but there is no evidence that jobs are created and destroyed at a more rapid rate in North America than they are in Europe. However, workers do appear to circulate faster through the existing jobs in North America (OECD, 1996, Tables 5.1, 5.2). This is also consistent with the finding that the United States has relatively high levels of regional mobility: about 3 percent of U.S. households change their region of residence in a year, compared to closer to 1 percent in the United Kingdom, Germany and France, and even lower in Italy and Spain. However, regional mobility rates in Norway and Sweden are similar to those in the United States (OECD, 1990, Table 3.3). Since the encouragement of regional mobility has always been a feature of Norwegian and Swedish labor market policy, this outcome is no surprise.<sup>3</sup>

A final perspective on the aggregate labor market is to look at the evidence on wage flexibility. Table 3 presents some measures of the responsiveness of overall wages to unemployment, derived from both aggregate time series and individual survey data. Of course, this is only one feature of wage flexibility; for example, it is not informative about the flexibility of relative wages across different groups. However, for this particular aspect of wage flexibility, there is no dramatic contrast between Europe and North America. If anything, Canada and the United States veer toward the inflexible end of the spectrum.

To summarize, the contrast between Europe and North America is more complex than is commonly realized. Unemployment is higher in the majority of European countries than in the United States, but there is considerable variation across Europe. Rates of job turnover are no higher in North America than in Europe and neither are overall wages any more flexible, but it does seem that U.S. workers are more mobile than are many Europeans both geographically and between jobs. The next step is to focus on a large number of separate features of the labor market and to try to isolate those that have some responsibility for the high levels of unemployment in many European countries.

### **What Features of the Labor Market Generate High Unemployment?**

Our aim in this section is to pinpoint precisely which features of the labor market generate unemployment and which do not. Then we can discuss how these facts relate to the view that high unemployment in Europe is due to rigid and inflexible labor markets.

The first step is to look at labor market characteristics in different countries. Table 4 presents direct measures of labor market rigidities and summary statistics

<sup>3</sup> The “regions” in all these countries are comparable in size, so these comparisons have some meaning.

Table 3

*Source:* Aggregate time series measures; Layard et al. (1991), chapter 9, Table 2. Microeconomic measures; Blanchflower and Oswald (1994), Table 9.1. These later numbers are derived by dividing the Blanchflower/Oswald numbers by the average unemployment rate, because they only report the elasticity of wages with respect to unemployment.

on the treatment of the unemployed. The employment protection index in the first column was drawn up by the OECD and is based on the strength of the legal framework governing hiring and firing. The countries are ranked from 1–20, with 20 being the most strictly regulated. The countries of southern Europe have the toughest regulations and, roughly speaking, these regulations get weaker as one moves further north. Switzerland, Denmark and the United Kingdom have the weakest laws in Europe, and these laws are comparable to those in place outside Europe.

The labor standards index in the second column was also drawn up by the OECD and refers to the strength of the legislation governing a number of aspects of the labor market. The index ranges from 0 to 10, with each country being scored from 0 (lax or no legislation) to 2 (strict legislation) on each of the five dimensions: working time, fixed-term contracts, employment protection, minimum wages and employees' representation rights (on works councils, company boards and the like). The scores are then added up. The picture is similar to the employment protection column. The United Kingdom and the United States have very weak legislation in this area, whereas Spain and Italy have many strict rules and regulations. So it is undoubtedly true that if we are to think of inflexibility as referring to legal restric-

tions on the operation of the labor market, southern and continental Europe are the most inflexible. As an offset to this, however, it is worth remarking that southern Europe also has the highest rate of self-employment in the OECD (OECD, 1994, Table 6.8). The self-employed are, presumably, among the most flexible of all workers.

Benefit systems vary quite dramatically. The “replacement rate,” which shows what share of income is replaced by unemployment benefits, and the duration of these benefits (four years means indefinite duration) are typically fairly generous by U.S. standards (50 percent replacement rate for six months). Italy, however, barely had an unemployment benefit system at all for most of the postwar period.<sup>4</sup>

<sup>4</sup> Until recently, the unemployed in Italy were entitled to 800 lira per day (around 50 cents). A small proportion of the “unemployed” would be covered by the CIG scheme for industrial workers who are in danger of being laid off. These typically do not amount to more than 1 percentage point of unemployment.

Some of the countries with the most generous benefit levels have strictly time-limited systems, notably in Scandinavia, like Sweden's 80 percent replacement rate, which is limited to 1.2 years. The next column, "active labor market policies," refers to expenditures on activities for the unemployed that are geared to help them back into work and are popular in many, although not all, European countries. These include labor market training, assistance with job search, subsidized employment and special measures for the disabled. The numbers in this column are derived by taking active labor market spending per unemployed person as a percentage of GDP per member of the labor force. Thus, Sweden's figure of close to 60 shows that expenditure on active policies per unemployed person is nearly 60 percent of national output per potential worker, which is extraordinarily high. Spain, on the other hand, is notable for its combination of a generous benefit system and a low level of expenditure on active labor market policies.

The first few columns of Table 5 present variables that summarize the structure of wage determination systems. In most European countries, with the exception of the United Kingdom and Switzerland, trade unions play a very significant role in wage determination. The union density column shows the proportion of trade union members as a percentage of all wage and salary earners. However, this does not tell the whole story. In many nations, union wage negotiations determine the wages of workers who are not explicitly part of the union. In Spain and France, for example, only about 10 percent of workers are union members, but the wages of over 70 percent of all workers are covered by union bargaining. Thus, the "union coverage index" presents a summary of the share of workers actually covered by union bargaining, where 3 means over 70 percent covered, 2 means from 25–70 percent, and 1 is under 25 percent.

The next column of the table shows the extent of coordination in wage bargaining, on the part of both unions and employers. In each country, the degree of union and then employer coordination is ranked from a low of 1 to a high of 3. In some of these countries, both unions and, more significantly, employers coordinate their wage bargaining activities, particularly in central Europe and Scandinavia. In those countries where unions play a lesser role, although still an important one—like the United Kingdom, Switzerland, and all non-European countries except the United States—there is very little coordination over wage bargaining, with the notable exceptions of Switzerland and Japan, where employer coordination is very important.

The final two columns of the table give information on the tax burden on labor. First we have the payroll tax rate, defined as the ratio of labor costs to wages (less unity) and then we show the total tax rate, which is the sum of the average payroll, income and consumption tax rates. The latter are based on aggregate tax and income data. The payroll tax rate varies dramatically across countries, with Denmark levying no payroll taxes and France and Italy with a rate close to 40 percent. The total tax rate is less variable and represents a crude measure of the tax wedge between real labor costs and real take-home pay. This is arguably the correct measure of the tax burden on labor.

Overall, therefore, there are quite substantial differences between European and North American labor markets as well as important differences within Europe. The consequences of these differences for unemployment and labor supply form our next topic.

## The Labor Market and Unemployment

Our purpose in what follows is to investigate the relations between unemployment and other measures of labor supply, and labor market institutions. Table 6 presents three regressions relating to unemployment. Each regression is based on two cross-sections dated 1983–88 and 1989–1994. The dependent variables are the unemployment rates reported in Table 1, and the values of the independent variables for the time period 1989–1994 are from Tables 4 and 5. The corresponding values of the independent variables for 1983–88 are not presented here but are available from the author. Some variables take the same values for both periods,

**Table 6**

Total Tax Rate (%)	0.026 (0.0087)	0.023 (0.013)	0.025 (0.010)
Change in Inflation (% pts. p.a.)	–0.17 (0.11)	–0.30 (0.17)	–0.18 (0.10)
Dummy for 1989–94	0.20 (0.095)	0.30 (0.16)	0.17 (0.089)
<i>R</i> <sup>2</sup>	0.76	0.84	0.60
<i>N</i> (countries, time)	40 (20, 2)	38 (19, 2)	38 (19, 2)

*Notes:* Estimation is by GLS random effects using two time periods (1983–88 and 1989–1994). Standard errors are in parentheses.

<sup>a</sup> The variable is instrumented. Because the active labor market policies variable refers to percentage of GDP normalized on *current* unemployment, this variable is highly endogenous. So we renormalized the current percentage of GDP spent on active labor market measures on the average unemployment rate in 1977–79 to create the instrument. Insofar as measurement errors in unemployment are serially uncorrelated, this will help with the endogeneity problem.

but many are different. We chose to use six-year averages in order to smooth out both the cycle and year-on-year noise. On the other hand, we felt there was enough useful information here to warrant the use of two cross-sections rather than one 12-year average. The regression coefficients are estimated using the standard random effects generalized least squares procedure, which is essentially ordinary least squares corrected for the fact that the two successive observations for each country cannot be treated as independent random draws. Finally, note that the dependent variables are the logs<sup>5</sup> of the unemployment rate (column 1), the long-term rate (column 2) and the short-term rate (column 3). Thus, if the right-hand side of the equation increases by 0.1, log unemployment goes up by 0.1, so unemployment rises by just over 10 percent. From a baseline unemployment rate of 5 percent, this would represent an increase of half a percentage point to 5.5 percent.

In Table 7 we report similar regressions explaining other aspects of labor supply, notably the employment/population ratios and overall labor supply reported

<sup>5</sup> The use of the log of the unemployment rate follows from the fact that many investigations of wage determination find that the use of  $\log u$  in a wage equation is preferable to the use of  $u$ . See Blanchflower and Oswald (1994), for example.

*Table 7*  
**Regressions to Explain Labor Supply Measures**  
*(20 OECD countries, 1983 and 1989–1994)*

	<i>Employment/Population Ratio (%)</i>		
	<i>1</i> <i>Whole Working</i> <i>Age Population</i>	<i>2</i> <i>Males Aged</i> <i>25–54</i>	<i>3</i> <i>Overall Labor</i> <i>Supply</i>

Replacement Rate (%)	–0.026 (0.072)	–0.052 (0.043)	–0.037 (0.091)
Benefit Duration (years)	–1.26 (0.63)	–0.61 (0.43)	–0.32 (0.73)
<sup>a</sup> Active Labour Market Policies	0.16 (0.11)	0.081 (0.073)	–0.028 (0.14)
Union Density (%)	–0.082 (0.086)	–0.11 (0.053)	–0.18 (0.11)
Union Coverage Index (1–3)	–0.96 (2.54)	–1.36 (1.74)	–2.24 (2.84)
Coordination (Union + Employer) (2–6)	5.03 (1.23)	2.71 (0.74)	4.20 (1.58)
Total Tax Rate (%)	–0.24 (0.12)	–0.16 (0.075)	–0.26 (0.16)
Change in Inflation (% pts. p.a.)	–2.12 (0.93)	–0.97 (0.72)	–2.02 (0.97)
Dummy for 1989–94	1.87 (0.79)	–2.09 (0.63)	0.041 (0.83)
<i>R</i> <sup>2</sup>	0.81	0.63	0.51
<i>N</i> (countries, time)	(20, 2)	(20, 2)	(20, 2)

*Notes:* Estimation is by GLS random effects using two time periods (1983, 1989–1994). Standard errors are in parentheses.

<sup>a</sup> Active labor market prices are instrumented as in Table 6.

in Table 2. Again we use two cross-sections with the same independent variables. In this case, the dependent variables are not in logs.

Before we go on to discuss particular rigidities, it is worth commenting briefly on the status of these results. First, we see them as a helpful overview of the correlations in the data and nothing more. Like all simple cross-section correlations, care must be taken with their interpretation because of issues of reverse causality and the like. Second, despite the use of six-year averages, there may still be significant long-term variations across countries in the stance of macroeconomic policy. We control for the average change in inflation as one attempt to deal with this problem. Third, there may be factors that explain cross-country differences in unemployment that are not associated with the labor market. For example, it can be argued that higher levels of product market competition tend to reduce unemployment (Layard, Nickell and Jackman, 1991, chapters 7 and 9, for example). Unfortunately, it has not proved possible to obtain measures of product market competition that are consistent across enough countries to include in the regressions.

Finally, and most importantly, why focus only on the 1980s and 1990s? Underlying this question is the reasonable argument that in the 1960s, the unemployment rankings across countries were completely different but, roughly speaking, the labor market institutions were the same. So how can the labor market institutions have

anything to do with unemployment? Part of the answer has to be that the institutions had a big impact on the way in which each of the economies of the different countries responded to the major adverse shocks of the 1970s *and* the way in which some of these responses, notably unemployment, persisted through the 1980s and 1990s. In part, this effect is what our regressions are picking up. There remain a number of unanswered questions concerning the evolution of labor markets since the 1960s. Here, our main concern is much more limited, namely the question of which institutions, for whatever reason, appear to be important in understanding recent unemployment levels across the OECD. So let us consider various institutions in turn.

### **Direct Rigidities**

Labor market legislation is typically put in place to protect employees from arbitrary, unfair or discriminatory actions on the part of employers. In so doing, it may raise the effective cost to firms of employing workers and/or raise the effective cost of adjusting levels of employment. The impact of the former on unemployment depends crucially on the extent to which the extra costs are shifted onto employees by a suitable adjustment of the wage. The general evidence on payroll taxes (as we shall see) is that the major part of the burden of such costs is typically shifted onto workers in the long run, thereby nullifying their impact on unemployment. While this obviously cannot be the case for minimum wages, there is no evidence in our data that high labor standards overall have any impact on unemployment whatever. For example, if we add our labor standards variable (Table 4, column 1) to our unemployment regression (Table 6, column 1), it has a negligible and completely insignificant coefficient.<sup>6</sup>

Laws that raise the cost of employment adjustment, notably those relating to employment protection, will tend to reduce the inflow into unemployment and, because they make firms more cautious about hiring, will also reduce the flow out of unemployment into work. This will almost certainly reduce short-term unemployment (via the reduced inflow) and raise long-term unemployment (via the reduced outflow). The overall impact on unemployment is likely to be rather small, as these effects would tend to cancel out. The results in the first row of Table 6 are entirely consistent with this discussion and confirm the analysis of Bentolila and Bertola (1990).

However, as the coefficients in the first row of Table 7, columns 1 and 3, indicate, there is some evidence of a negative correlation between employment protection and measures of labor supply that go beyond unemployment (see also Lazaar, 1990). Much of this correlation arises, in fact, because participation rates among married women in southern Europe are very low and employment protection laws in these countries are very tough (OECD, 1994, Table 6.9). Thus, as the first row of Table 7 also indicates, if we focus on prime-age men (column 2), there

<sup>6</sup> The coefficient is 0.019 with a standard error of 0.063.

is no effect. A speculative hypothesis might be that low female participation and tough employment protection laws in southern Europe are both consequences of a culture that places a great deal of weight on the position of the (male) head of household, which is not to be undermined either by the presence of a high-earning wife or by the loss of a job.

### **The Treatment of the Unemployed**

There are two aspects of the treatment of unemployed individuals, which might be termed passive and active. The passive is exemplified by the payment, as of right, of unemployment benefit for a given period. Active policies, on the other hand, consist of measures that attempt to ensure that the unemployed individual is able and willing to take up work.

On the passive side, generous benefit systems influence unemployment via two mechanisms. First, they reduce the fear of unemployment and hence directly increase upward pressure on wages from employees (via unions, for example). Second, they reduce the “effectiveness” of unemployed individuals as potential fillers of vacancies, by allowing them to be more choosy. The impact of a high benefit replacement ratio on unemployment is well documented (Layard, Nickell and Jackman, 1991; OECD, 1994, chapter 8) and is confirmed by the significant coefficient on the replacement rate in Table 6. The other important feature of the benefit system is the duration of entitlement. Long-term benefits generate long-term unemployment (Table 6, row 3; OECD, 1991, Chart 7.1B). Of course, it can be argued that countries might introduce more generous benefit systems when unemployment is a serious problem, so that in cross-country correlations, the causality runs from unemployment to benefits rather than the other way round. However, the microeconomic evidence on the positive impact of benefit levels and entitlement durations on the duration of individual unemployment spells (Narendranathan, Nickell and Stern, 1985; Meyer, 1990) suggests that at least part of the observed cross-country correlation can be taken at face value.

The impact of a relatively generous benefit system might be offset by suitable active measures to push the unemployed back to work. Such policies seem to work particularly well when allied to a relatively short duration of benefit entitlement, reducing long-term unemployment while alleviating the social distress that might be caused by simply discontinuing benefits without offering active assistance toward a job. Their effects are well summarized in OECD (1993, ch. 2), and their significant impact in reducing long-term unemployment is illustrated in the fourth row of Table 6.

While benefits affect unemployment, our evidence suggests that the benefit system seems to have little impact on overall labor supply as shown in Table 7. There is a suggestion here that while high benefits lead to high unemployment, they also lead to high participation because they make participation in the labor market more attractive, because participation is necessary to be eligible for the high benefits. This is consistent with a weak impact of benefits on employment/popu-

lation ratios, because the higher unemployment effect and the higher labor market participation effect tend to cancel out.

### **Wage Determination and Unions**

The key features of wage determination systems are the extent to which wages are determined collectively, via union bargaining (union coverage), and the degree to which employers and unions coordinate their wage bargaining activities given that wages are determined collectively. Of course, if wages are not generally determined collectively, as in the United States, the extent of coordination simply does not apply.

Unions tend to raise pay, and thus one would expect the extent of union activity in an economy to influence unemployment. This is confirmed by the results in rows 5 and 6 of Table 6, where greater union density and especially union coverage tend to raise unemployment. However, Table 6, row 7, also shows that this is offset if unions and employers can coordinate their bargaining activities. For example, leapfrogging is a common feature of decentralized, uncoordinated, union-dominated systems; that is, each union tends to take an earlier pay settlement in a related sector as a baseline to be exceeded in its own negotiations. This generates an additional source of inflationary pressure that requires more unemployment to quash it. If unions and employers can coordinate their wage bargaining activities, such leapfrogging may be eliminated.

It is important to note that coordination does not mean centralization, which typically implies government involvement in wage bargaining. Both Japan and Germany have a high degree of coordination in wage bargaining, particularly across employers, but neither system is centralized. And as OECD (1994, Table 5.16) makes clear, coordination appears to have a significant negative impact on wages, whereas the centralization of wage bargaining does not. To summarize, therefore, unions are bad for jobs, but these bad effects can be nullified if both the unions and the employers can coordinate their wage bargaining activities.

### **Labor Taxes**

Lowering payroll taxes is a very popular recommendation by those concerned with reducing unemployment (OECD, 1994; Phelps, 1994). It is easy to understand this advice if a payroll tax is viewed as a tax on jobs. Things are not, however, quite as they seem. The first point to recognize is that, broadly speaking, the key tax rate for the labor market is the sum of the payroll tax rate, the personal income tax rate and the consumption tax rate. Switching between these taxes will not have an important impact, so payroll taxes, per se, are of little consequence. This result has nothing to do with the incidence of these taxes, which we shall address later. It derives from the logic of supply and demand.

Consider a simple example. Suppose we have a labor market where total labor costs per employee are \$100, payroll taxes paid by the employer are \$10 (so pretax wages are \$90), income taxes paid by the employee are \$10, and post-tax wages are \$80. Suppose this labor market is in equilibrium. Thus, firms are just willing to

employ at \$100 all the workers who are willing to work at \$80. Now suppose that income taxes are reduced to \$5 and payroll taxes are raised to \$15 to maintain revenue. Further, suppose that as a result of this change, firms pay pretax wages of \$85. Then labor costs per employee are \$100; post-tax wages are \$80. This remains an equilibrium because firms are still willing to employ at \$100 all the workers who want to work at \$80. Nothing substantive has changed except that pretax wages have fallen from \$90 to \$85. But this is irrelevant; the only prices that interest the agents in this economy are labor costs per employee and post-tax wages.

But what about consumption taxes? Employees are interested in what their wages can buy. So if their income taxes are cut by 10 percent and the cost of consumption is raised by 10 percent, post-tax real wages are unchanged and so is labor market behavior. So, broadly speaking, what really counts is the sum of payroll taxes, income taxes and consumption taxes; the total tax burden on labor. Of course, this is not exactly correct for a variety of reasons. For example, income tax is charged on nonlabor income whereas payroll tax is not, so that a cut in payroll tax and a rise in income tax will reduce nonlabor income, raise labor supply and reduce unemployment. But, in practice, this is not important because individuals who are likely to become unemployed have little or no nonlabor income.<sup>7</sup> Our conclusion is that payroll taxes, *per se*, can be expected to have little impact on unemployment but the total tax burden might.

The fundamental question, therefore, is whether or not this total tax burden is entirely shifted onto labor. That is, does real labor cost per worker remain unaffected by variations in the total tax burden, at least in the long run?

If capital is internationally mobile and labor is not, then we should expect to see labor bearing all of the tax burden. In this case, employment and unemployment will, in the long run, remain unaffected by changes in the overall tax rate on labor. There is, however, one situation where it is impossible to shift payroll taxes onto workers. That is where there is a rise in the payroll tax and an employee is already receiving the minimum wage. The burden of the extra tax must then fall on the employer because the wage cannot adjust.

What happens in practice? The balance of the evidence suggests that lowering payroll taxes and raising consumption taxes will have no long-run impact on unemployment (OECD, 1990, Annex 6A; OECD, 1994, Table 9.5).<sup>8</sup> This result is confirmed by the fact that if we include the payroll tax rate in any of the regressions in Table 6 or 7, its coefficient is always negligible.<sup>9</sup> It also helps to explain why Denmark, which uniquely has no payroll taxes, has unemployment on a par with

<sup>7</sup> For example, in Britain in 1987–88, only 7 percent of the unemployed had savings in excess of 3,000 pounds, enough to produce an annual interest income of around 10 percent of unemployment benefit (Layard, Nickell and Jackman, 1991, Table A6).

<sup>8</sup> There are some individual country time series results that appear to give a role to payroll taxes in individual countries—see OECD (1994, Chapter 9, p. 247) for a summary. However, in relatively short time series, it is often very difficult to distinguish between long-lasting short-run effects and long-run effects.

<sup>9</sup> For example, in columns of Table 6 its coefficient is -0.014, with a standard error of 0.06.

the European average and appears to derive no special employment benefit from its lack of these taxes.

The evidence on the total tax burden is less clear. One careful cross-country study has ruled out any long-run impact of the total tax burden on employment (OECD, 1990, Annex 6A). However, the results in Tables 6 and 7, row 8, which are in agreement with the findings of Bean, Layard and Nickell (1986), suggest that the overall tax burden may raise unemployment and reduce labor supply. A 10 percentage point fall in the total tax burden reduces unemployment by around 25 percent and raises labor supply by around 2 percentage points on every measure. Of course, a 10 percentage point fall in the total tax burden is enormous. Most countries find permanently reducing expenditure by 1 percent of GDP an extremely difficult task. To generate a 10 percentage point shift would mean, for example, transferring the whole of the UK health service to the private sector.<sup>10</sup>

### **Minimum Wages**

While it is impossible to produce a single cross-country variable that captures the impact of minimum wage laws or related legislation (like extending union pay bargains to the nonunion sector), it is still worth discussing the potential impact of minimum wages on unemployment. A reading of Card and Krueger (1995) and its various reviews in the July 1995 issue of the *Industrial and Labor Relations Review* reveals that there is no consensus on the impact of minimum wages on unemployment. However, the following conclusions do seem to be consistent with the evidence. First, where the minimum wage applies, it is low enough not to have an important effect on the unemployment rates of adult men. Second, minimum wages do have a significant though small adverse impact on youth unemployment rates, particularly in countries like France and Spain where payroll taxes are high and there is little in the way of an age adjustment to the minimum wage (Dolado et al., 1996; Abowd et al., 1996).

### **Labor Supply Measures**

Two much-canvassed solutions to unemployment are reduced hours of work and early retirement. Advocates of these measures often seem to imagine that there is some exogenously given level of work to be done. In fact, all historical evidence shows that, for a given institutional structure, the amount of work to be done tends to adjust in line with the available supply of labor, leaving equilibrium unemployment unaffected. So we can expect that an *imposed* cut in hours or reduction in the labor force will raise wage pressure in a way that can only be offset by an equivalent cut in jobs. Indeed if, in a standard wage equation, we allow wages to depend

<sup>10</sup> Even if there were some macroeconomic benefits to this, there could easily be substantial costs; for example, total health expenditure in the United Kingdom is 4–5 percentage points of GDP less than health expenditure in the United States, without there being notable differences in the overall health of the two populations. Moving health care to the private sector might impair efforts to hold down costs, or result in greater inefficiency.

separately on (the logs of) labor force and employment instead of on unemployment, we typically obtain equal and opposite coefficients. This indicates that a fall in the labor force relative to employment raises wage pressure just as much as a rise in employment relative to the labor force (Layard, Nickell and Jackman, 1991, p. 504; Jackman, Layard and Nickell, 1996, p. 28). Similarly, if one adds measures of labor supply like hours worked per worker to the unemployment regressions in Table 6, no significant effect is found.

### **Shifts in the Demand for Skills and Unemployment**

It has become commonplace to argue: “The rise in joblessness in Europe is thus the flip side of the rise in earnings inequality in the U.S.” (Freeman, 1995, p. 19). This view is based on the notion that first, in all countries, there has been an increase in the relative demand for skilled workers (as against unskilled workers) that has been greater than the increase in their relative supply. Then the argument goes that in Europe, the inflexibility of the labor market has turned this shift into higher unemployment whereas in the United States, labor market flexibility has translated this shift into increased inequality. Finally, this shift explains the majority of the rise in European unemployment relative to that in the United States.

Despite this being a commonly held view, a variety of facts cast doubt on it (Card, Kramarz and Lemieux, 1995; Nickell and Bell, 1995, 1996; Nickell, 1996; Jackman et al., 1996). First, it appears to be the case that in Britain and the United States the demand for skill outran the supply by more than in the rest of Europe. Second, for a variety of European countries including Britain, the evidence suggests that skill shifts account for between 0 and 20 percent of the rise in unemployment from the 1970s. There is no evidence that this number is lower in “flexible” Britain than it is anywhere else in Europe. In any event, the vast majority of the rise in European unemployment is due to other factors. Third, there has been a substantial rise in unskilled unemployment in the United States since the early 1970s (over 100 percent) despite (because of?) the fall in unskilled real wages. Fourth, the adverse impact of the fall in the relative demand for unskilled workers on the wages and unemployment of this group is strongly attenuated in those countries whose education and training systems are particularly effective at raising the human capital of those at the lower end of the ability range (notably middle Europe<sup>11</sup> and Scandinavia).

Overall, therefore, there is no evidence that these skill shifts have made a substantial contribution to the rise in European unemployment nor that labor market inflexibility per se is associated in any simple way with such effects as have been observed.

### **Special Cases and the Demand Side**

Our aim has been to understand what generates high average levels of unemployment over long periods. Business cycle effects and autonomous demand shocks of

<sup>11</sup> That is, Switzerland, Austria, Germany and Holland.

various kinds should wash out if we take a long enough period—and our focus has been on 1983–1996, a 14-year stretch. Despite the length of this period, it is possible to argue that because of exceptional problems, policy mismanagement, very high levels of hysteresis and the like, the average unemployment figures give a distorted picture of the underlying equilibrium rate. If we were just considering the 1990s, this argument might be applied to a number of countries, such as Sweden. But over the longer period, there is only one country where truly exceptional problems have distorted the long period average dramatically, namely Finland. In the three years from 1990 to 1993, Finnish unemployment rose from 3.4 to 17.7 percent. This increase was generated first by the collapse of an enormous domestic credit boom, which was, in its turn, brought about by a mismanaged deregulation of the financial sector. Real house prices fell by over 50 percent between 1990 and 1993. This disaster was reinforced by the more or less complete elimination of Soviet trade over the same period, which had previously been responsible for about one-third of Finnish exports. Without these exceptional events, there is no question that average unemployment would have been substantially lower over the relevant period and this lower number would more accurately reflect the equilibrium rate in Finland.

## Conclusions

High unemployment is associated with the following labor market features: 1) generous unemployment benefits that are allowed to run on indefinitely, combined with little or no pressure on the unemployed to obtain work and low levels of active intervention to increase the ability and willingness of the unemployed to work; 2) high unionization with wages bargained collectively and no coordination between either unions or employers in wage bargaining; 3) high overall taxes impinging on labor or a combination of high minimum wages for young people associated with high payroll taxes; and 4) poor educational standards at the bottom end of the labor market.

Labor market rigidities that do not appear to have serious implications for average levels of unemployment include the following: 1) strict employment protection legislation and general legislation on labor market standards; 2) generous levels of unemployment benefit, so long as these are accompanied by pressure on the unemployed to take jobs by, for example, fixing the duration of benefit and providing resources to raise the ability/willingness of the unemployed to take jobs; and 3) high levels of unionization and union coverage, so long as they are offset by high levels of coordination in wage bargaining, particularly among employers.

Suppose we define high unemployment as above 120 percent of the U.S. rate over the 1983–1996 period (7.8 percent). Then, looking at Table 1, we see there are eight European countries in this category out of 15, as well as Canada. These eight include three major countries (France, Spain and United Kingdom) of which the last has far and away the most flexible labor market in Europe, as normally measured. The remaining countries with high unemployment are Belgium, Denmark, Finland, Ireland and the Netherlands.

Unemployment is high in these countries (excluding Finland, for reasons already explained) partly because, on average, they have reasonably generous benefits with very long periods of entitlement and little in the way of active policies to push the unemployed into work. Wages are typically bargained collectively, so unions apply pressure on wages, but coordination is not high, particularly among employers. Education levels at the lower end of the ability range are generally weak. Of course, not all of these apply to every country, and the country to which they apply least, the Netherlands, is now moving out of the high-unemployment group. Most importantly for the topic of this paper, many features of the labor market that are popularly viewed as serious rigidities apply no more to this high-unemployment group than they do to the low-unemployment group. These include high payroll taxes, high overall taxes, strict employment protection legislation, high labor market standards (legally enforced), high unionization and high benefit replacement rates.

It is clear that the broad-brush analysis that says that European unemployment is high because European labor markets are “rigid” is too vague and probably misleading. Many labor market institutions that conventionally come under the heading of rigidities have no observable impact on unemployment.

■ *I am most grateful to Tracy Jones and the Leverhulme Trust (Programme on Unemployment and Technical and Structural Change) for their help in the preparation of this paper. My thanks are also due to Alan Krueger, Bradford De Long and Timothy Taylor for their very useful comments on an earlier draft.*
